It is possible to show that the operator T is a contraction mapping on $\mathbb{R}^n$ so that it has a unique fixed point and the sequence of vectors $\{J^k\}_k$ with $J^{k+1} = TJ^k$ converge to the unique fixed point of the operator T . Since the value function J^* is a fixed point of the operator T , the value iteration algorithm indeed converges to J^* .

Policy Iteration Algorithm

The sequence of vectors $\{J^k\}_k$ generated by the value iteration algorithm do not necessarily correspond to the discounted cost $J^\pi = \{J^\pi(i) : i \in \mathcal{S}\}$ incurred by some policy π . In

contrast, the policy iteration algorithm generates a sequence of vectors that correspond to the discounted costs incurred by different policies. To describe the policy iteration algorithm, for $J \in \mathbb{R}^n$ and $\pi \in \Pi$, we define the linear operator T_π on $\mathbb{R}^n$ as

$$[T_\pi J](i) = \sum_{j \in S} p_{ij}(\pi(i)) [g(i, \pi(i), j) + \alpha J(j)]. \quad (3)$$

In this case, it is possible to show that the discounted cost J^π incurred by policy π is a fixed point of the operator T_π satisfying $J^\pi = T_\pi J^\pi$. Since the operator T_π is linear, we can find a fixed point of this operator by solving a system of linear equations. In particular, if we let P^π be the transition probability matrix $\{p_{ij}(\pi(i)) : i, j \in S\}$, $g^\pi(i) = \sum_{j \in S} p_{ij}(\pi(i)) g(i, \pi(i), j)$ be the expected cost that we incur when we are in state i and follow policy π and $g^\pi = \{g^\pi(i) : i \in S\}$ be the vector of expected costs, then $T_\pi J$ in Equation (3) can be written in vector notation as

$$T_\pi J = g^\pi + \alpha P^\pi J.$$

Therefore, we can find a J^π that satisfies $J^\pi = T_\pi J^\pi$ by solving the system of linear equations $J^\pi = g^\pi + \alpha P^\pi J^\pi$, which has the solution $J^\pi = (I - \alpha P^\pi)^{-1} g^\pi$, where I denotes the $n \times n$ identity matrix and the superscript -1 denotes the matrix inverse. The policy iteration algorithm computes the optimal policy by starting from an initial policy π^1 and generating a sequence of policies $\{\pi^k\}_k$ through the following two steps.

Step 1 [Policy Evaluation]. Compute the discounted cost J^{π^k} incurred by policy π^k , possibly by solving the system of linear equations $J^{\pi^k} = g^{\pi^k} + \alpha P^{\pi^k} J^{\pi^k}$.

Step 2 [Policy improvement]. For all $i \in S$, let policy π^{k+1} be defined such that we have

$$\begin{aligned} \pi^{k+1}(i) &= \operatorname{argmin}_{u \in \mathcal{U}(i)} \left\{ \sum_{j \in S} p_{ij}(u) [g(i, u, j) + \alpha J^{\pi^k}(j)] \right\}. \end{aligned} \quad (4)$$

Noting the definition of the operator T , policy π^{k+1} that is obtained in Step 2 satisfies $TJ^{\pi^k} = T_{\pi^{k+1}}J^{\pi^k}$. The algorithm stops when the policies at two successive iterations satisfy $\pi^k = \pi^{k+1}$. If we have $\pi^k = \pi^{k+1}$, then we obtain $TJ^{\pi^k} = T_{\pi^{k+1}}J^{\pi^k} = T_{\pi^k}J^{\pi^k} = J^{\pi^k}$ so that J^{π^k} is a fixed point of the operator T , which implies that J^{π^k} is the solution to the optimality equation (1). In the last chain of equalities, the first equality follows by the definition of the policy iteration algorithm, the second equality follows by the fact that $\pi^{k+1} = \pi^k$ at termination, and the last equality follows by the fact that the discounted cost incurred by policy π^k is the fixed point of the operator T_{π^k} .

The value and policy iteration algorithms are perhaps the most standard approaches for solving Markov decision problems, but they quickly lose their computational tractability. If the number of states is large, then computing and storing J^k in the value iteration algorithm and J^{π^k} in the policy iteration algorithm becomes difficult. Furthermore, if the number of actions is large, then solving the optimization problems in Equations (2) and (4) becomes intractable. Finally, solving these optimization problems requires computing expectations according to certain transition probability matrices and leaving the computation of such expectations aside, it can be very costly to even estimate and store the transition probability matrices. Throughout this article, we try to resolve these difficulties by giving algorithms that tend to be computationally more appealing than the value and policy iteration algorithms.

The books by Puterman [9] and Bertsekas [10] are modern and complete references on the theory of Markov decision processes. The notation that we use in this article follows that in Bertsekas [10] closely. Early analysis of the value iteration algorithm is attributed to Shapley [11] and Blackwell [12], whereas the policy iteration algorithm dates back to Bellman [13] and Howard [14]. Bellman [13] coins the term *curse of dimensionality* to refer to the difficulty associated with the large number of states, especially when the state is itself a high dimensional vector. Powell [4]

observes that not only the number of states, but also the number of admissible actions and the necessity to compute expectations can create computational difficulties.

There are a number of extensions for the value and policy iteration algorithms. It is possible to characterize the convergence rate of the value iteration algorithm and use this result to estimate the number of iterations to compute the value function with a certain precision. There is a Gauss Seidel variant of the value iteration algorithm that applies the operator T in an asynchronous manner. Modified policy iteration algorithm evaluates a policy only approximately in the policy evaluation step. There are methods to eliminate the suboptimal actions and such methods ensure that the operator T can be applied faster. Furthermore, the sequence of vectors generated by the value iteration algorithm converge to the value function only in the limit, but the action elimination methods may allow identifying the optimal policy without waiting for the value iteration algorithm to converge to the value function. We focus on problems with finite state and action spaces under the discounted cost criterion, but extensions to more general state and action spaces under average cost and undiscounted cost criteria are possible. Bertsekas [5], Puterman [9], Bertsekas [10,15], and Sennott [16] are good references to explore the extensions that we mention in this paragraph.

POLICY EVALUATION WITH MONTE CARLO SIMULATION

In many cases, it is necessary to compute the discounted cost J^π incurred by some policy π . Computing the discounted cost incurred by a policy requires solving a system of linear equations of the form $J^\pi = g^\pi + \alpha P^\pi J^\pi$ and solving this system may be difficult, especially when the dimensions of the matrices are too large or when we simply do not have the data to estimate the transition probability matrix P^π . In these situations, we may want to use simulation to estimate the discounted cost incurred by a particular policy.

Assume that we generate a sequence of states $\{i_0, i_1, \dots\}$ by following policy π , which

is the policy that we want to evaluate. The initial state i_0 is chosen arbitrarily and the state transitions are sampled from the transition probability matrix P^π associated with policy π . Noting the discussion in the paragraph above, we may not have access to the full transition probability matrix P^π , but the sequence of states $\{i_0, i_1, \dots\}$ may be generated either by experimenting with the system in real time or by making use of the data related to the evolution of the system in the past. Since the sequence of states $\{i_0, i_1, \dots\}$ come from the transition probability matrix P^π , the discounted cost J^π incurred by policy π satisfies $J^\pi(i_k) = \mathbb{E}\{g(i_k, \pi(i_k), i_{k+1}) + \alpha J^\pi(i_{k+1})\}$. In this case, we can keep a vector $J \in \mathbb{R}^n$ as an approximation to J^π and update one component of this vector after every state transition by

$$J(i_k) \leftarrow (1 - \gamma)J(i_k) + \gamma[g(i_k, \pi(i_k), i_{k+1}) + \alpha J(i_{k+1})], \quad (5)$$

where $\gamma \in [0, 1]$ is a step size parameter. The idea behind the updating procedure above is that $J(i_k)$ on the right side of Equation (5) is our estimate of $J^\pi(i_k)$ just before the k th state transition. Noting that $J^\pi(i_k) = \mathbb{E}\{g(i_k, \pi(i_k), i_{k+1}) + \alpha J^\pi(i_{k+1})\}$, if J and J^π are close to each other, then $g(i_k, \pi(i_k), i_{k+1}) + \alpha J(i_{k+1})$ can be interpreted as a noisy estimate $J^\pi(i_k)$ that we obtain during the k th state transition. Therefore, the updating procedure in Equation (5) combines the current estimate and the new noisy estimate by putting the weights $1 - \gamma$ and γ on them. This kind of an updating procedure is motivated by the standard stochastic approximation theory and if the step size parameter γ converges to zero at an appropriate rate, then it is possible to show that the vector J converges to J^π with probability 1 as long as every state is sampled infinitely often.

The simulation-based approach outlined above does not require storing of the transition probability matrix, but it still requires storing of the n dimensional vector J , which can be problematic when the number of states is large. One approach to alleviate this storage requirement is to use a parameterized approximation architecture. In particular, we

approximate $J^\pi(i)$ with

$$\tilde{J}(i, r) = \sum_{\ell=1}^L r_\ell \phi_\ell(i), \quad (6)$$

where $\{\phi_\ell(\cdot) : \ell = 1, \dots, L\}$ are fixed functions specified by the model builder and $r = \{r_\ell : \ell = 1, \dots, L\}$ are adjustable parameters. We can view $\{\phi_\ell(i) : \ell = 1, \dots, L\}$ as the features of state i that are combined in a linear fashion to form an approximation to $J^\pi(i)$. For this reason, it is common to refer to $\{\phi_\ell(\cdot) : \ell = 1, \dots, L\}$ as the *feature functions*. The goal is to tune the adjustable parameters r so that $\tilde{J}(\cdot, r)$ is a good approximation to J^π . There are a number of algorithms to tune the adjustable parameters. One simulation-based approach iteratively updates the vector $r = \{r_\ell : \ell = 1, \dots, L\} \in \mathbb{R}^L$ after every state transition by

$$\begin{aligned} r &\leftarrow r + \gamma [g(i_k, \pi(i_k), i_{k+1}) \\ &\quad + \alpha \tilde{J}(i_{k+1}, r) - \tilde{J}(i_k, r)] \nabla_r \tilde{J}(i_k, r) \\ &= r + \gamma [g(i_k, \pi(i_k), i_{k+1}) + \alpha \tilde{J}(i_{k+1}, r) \\ &\quad - \tilde{J}(i_k, r)] \phi(i_k) \end{aligned} \quad (7)$$

where we use $\nabla_r \tilde{J}(i_k, r)$ to denote the gradient of $\tilde{J}(i_k, r)$ with respect to r and $\phi(i_k)$ to denote the L dimensional vector $\{\phi_\ell(i_k) : \ell = 1, \dots, L\}$. The equality above simply follows by the definition of $\tilde{J}(i_k, r)$ given in Equation (6).

Bertsekas and Tsitsiklis [1] justify the updating procedure in Equation (7) as a stochastic gradient iteration to minimize the squared deviation between the discounted cost approximation $\tilde{J}(\cdot, r)$ and the simulated cost trajectory of the system. They are able to provide convergence results for this updating procedure, but as indicated by Powell [4], one should be careful about the choice of the step size parameter γ to obtain desirable empirical convergence behavior. Another way to build intuition into the updating procedure in Equation (7) is to consider the case where $L = n$ and $\phi_\ell(i) = 1$ whenever $\ell = i$ and $\phi_\ell(i) = 0$ otherwise, which implies that we have $\tilde{J}(i, r) = r_i$ for all $i \in \{1, \dots, n\}$. This situation corresponds to the case where the number of feature

functions is as large as the number of states and the discounted cost approximation $\tilde{J}(\cdot, r)$ in Equation (6) can exactly capture the actual discounted cost J^π . In this case, $\phi(i_k)$ becomes the n dimensional unit vector with a one in the i_k th component and the updating procedure in Equation (7) becomes $r_{i_k} \leftarrow r_{i_k} + \gamma [g(i_k, \pi(i_k), i_{k+1}) + \alpha r_{i_{k+1}} - r_{i_k}]$. We observe that the last updating procedure can be written as $r_{i_k} \leftarrow (1 - \gamma) r_{i_k} + \gamma [g(i_k, \pi(i_k), i_{k+1}) + \alpha r_{i_{k+1}}]$, which is identical to Equation (5). Therefore, if the number of feature functions is as large as the number of states, then the updating procedures in Equations (5) and (7) become equivalent.

We can build on the ideas above to construct more sophisticated tools for simulation-based policy evaluation. The preceding development is based on the fact that J^π satisfies $J^\pi(i_k) = \mathbb{E}[g(i_k, \pi(i_k), i_{k+1}) + \alpha J^\pi(i_{k+1})]$, but it is also possible to show that J^π satisfies

$$\begin{aligned} J^\pi(i_k) &= \mathbb{E} \left\{ \frac{\sum_{l=k}^{\tau-1} (\lambda \alpha)^{l-k} [g(i_l, \pi(i_l), i_{l+1})] \right. \\ &\quad \left. + \alpha J^\pi(i_{l+1}) - J^\pi(i_l) \right\} \\ &\quad + J^\pi(i_k), \end{aligned}$$

for any stopping time τ and any $\lambda \in (0, 1]$. The identity above can be seen by noting that the expectation of the expression in the square brackets is zero, but a more rigorous derivation can be found in Bertsekas and Tsitsiklis [1]. This identity immediately motivates the following stochastic approximation approach to keep and update an approximation $J \in \mathbb{R}^n$ to the discounted cost J^π . We generate a sequence of states $\{i_0, i_1, \dots, i_\tau\}$ by following policy π until the stopping time τ . Once the entire simulation is over, letting $d_l = g(i_l, \pi(i_l), i_{l+1}) + \alpha J(i_{l+1}) - J(i_l)$ for notational brevity, we update the approximation $J \in \mathbb{R}^n$ by

$$J(i_k) \leftarrow J(i_k) + \gamma \sum_{l=k}^{\tau-1} (\lambda \alpha)^{l-k} d_l, \quad (8)$$

for all $\{i_k : k = 0, \dots, \tau - 1\}$. After updating J , we generate another sequence of states until the stopping time τ and continue in a similar fashion. When $\lambda = 1$ and τ deterministically

takes the value 1, the updating procedures in Equations (5) and (8) become equivalent.

The quantity d_l is referred to as the *temporal difference* and the updating procedures similar to that in Equation (8) are called *temporal difference learning*. For different values of $\lambda \in [0, 1]$, we obtain a whole class of algorithms and this class of algorithms is commonly denoted as TD(λ). The approach that we describe above works in batch mode in the sense that it updates the approximation for a number of states after each simulation trajectory is over and it can be viewed as an offline version. There are also online versions of TD(λ) that update the approximation after every state transition. If the number of states is large, then carrying out the updating procedure in Equation (8) for TD(λ) can be difficult as it requires storing of the n dimensional vector J . It turns out that one can use a parameterized approximation architecture similar to that in Equation (6) to alleviate the storage problem. In this case, we update the L dimensional vector r of adjustable parameters by using

$$r \leftarrow r + \gamma \sum_{k=0}^{\tau-1} \nabla_r \tilde{J}(i_k, r) \sum_{l=k}^{\tau-1} (\lambda \alpha)^{l-k} d_l, \quad (9)$$

where the temporal difference above is defined as $d_l = g(i_l, \pi(i_l), i_{l+1}) + \alpha \tilde{J}(i_{l+1}, r) - \tilde{J}(i_l, r)$. Similar to the updating procedure in Equation (7), we can build intuition for the updating procedure in Equation (9) by considering the case where $L = n$ and $\phi_\ell(i) = 1$ whenever $\ell = i$ and $\phi_\ell(i) = 0$ otherwise. In this case, it is not difficult to see that the updating procedures in Equations (8) and (9) become equivalent.

Temporal difference learning has its origins in Sutton [17,18]. The presentation in this section is based on Bertsekas and Tsitsiklis [1], where the authors give convergence results for numerous versions of TD(λ), including online and offline versions with different values for λ , applied to infinite horizon discounted cost and stochastic shortest path problems. The book authored by Sutton [2] is another complete reference on temporal difference learning. Tsitsiklis and Van Roy [19] analyze temporal difference learning with parameterized approximation architectures.

MODEL-FREE LEARNING

Assuming that we have a good approximation to the value function, to be able to choose an action by using this value function approximation, we need to replace the vector J in the right side of the optimality equation (1) with the value function approximation and solve the resulting optimization problem. This approach requires computing an expectation that involves the transition probabilities $\{p_{ij}(u) : i, j \in S, u \in \mathcal{U}\}$. We can try to estimate this expectation by using simulation, but it is natural to ask whether we can come up with a method that bypasses estimating expectations explicitly. This is precisely the goal of model-free learning, or more specifically the Q-learning algorithm.

The Q-learning algorithm is based on an alternative representation of the optimality equation (1). If we let $Q(i, u) = \sum_{j \in S} p_{ij}(u) [g(i, u, j) + \alpha J(j)]$, then Equation (1) implies that $J(i) = \min_{u \in \mathcal{U}(i)} Q(i, u)$ and we can write the optimality equation (1) as

$$Q(i, u) = \sum_{j \in S} p_{ij}(u) [g(i, u, j) + \alpha \min_{v \in \mathcal{U}(j)} Q(j, v)]. \quad (10)$$

In this case, if $Q^* = \{Q^*(i, u) : i \in S, u \in \mathcal{U}(i)\}$ is a solution to the optimality equation above, then it is optimal to take the action $\arg \min_{u \in \mathcal{U}(i)} Q^*(i, u)$ when the system is in state i . One interpretation of $Q^*(i, u)$ is that it is the optimal discounted cost given that the system starts in state i and the first action is u . The fundamental idea behind the Q-learning algorithm is to solve the optimality equation (10) by using a stochastic approximation iteration. The algorithm generates a sequence of states and actions $\{i_0, u_0, i_1, u_1, \dots\}$ such that $u_k \in \mathcal{U}(i_k)$ for all $k = 0, 1, \dots$. It keeps an approximation $Q \in \mathbb{R}^{n \times |\mathcal{U}|}$ to Q^* and updates this approximation after every state transition by

$$Q(i_k, u_k) \leftarrow (1 - \gamma) Q(i_k, u_k) + \gamma [g(i_k, u_k, s_k) + \alpha \min_{v \in \mathcal{U}(s_k)} Q(s_k, v)], \quad (11)$$

where the successor state s_k of i_k is sampled according to the probabilities $\{p_{i_k j}(u_k) : j \in S\}$. The rationale behind the

updating procedure above is similar to that in Equation (5) in the sense that $Q(i_k, u_k)$ on the right side of Equation (11) is our current estimate of $Q^*(i_k, u_k)$ just before the k th state transition and the expression in the square brackets is our new noisy estimate of $Q^*(i_k, u_k)$. If every state action pair is sampled infinitely often in the trajectory of the system and the step size parameter γ satisfies certain conditions, then it can be shown that the approximation kept by the Q-learning algorithm converges to the solution to the optimality equation (10).

For the convergence result to hold, the sequence of states and actions $\{i_0, u_0, i_1, u_1, \dots\}$ can be sampled in an arbitrary manner as long as every state action pair is sampled infinitely often. However, the Q-learning algorithm is often used to control the real system as it evolves in real time. In such situations, given that the system is currently in state i_k , it is customary to choose $u_k = \operatorname{argmin}_{u \in \mathcal{U}(i_k)} Q(i_k, u)$, where Q is the current approximation to Q^* . The hope is that if the approximation Q is close to Q^* , then the action u_k is the optimal action when the system is in state i_k . After implementing the action u_k , the system moves to some state i_{k+1} and it is also customary to choose the successor state s_k in the updating procedure in Equation (11) as i_{k+1} . The reason behind this choice is that after implementing the action u_k in state i_k , the system naturally moves to state i_{k+1} according to the transition probabilities $\{p_{i_k, j}(u_k) : j \in S\}$ and choosing $s_k = i_{k+1}$ ensures that the successor state s_k is also chosen according to these transition probabilities. To ensure that every state action pair is sampled infinitely often, with a small probability, the action u_k is randomly chosen among the admissible actions instead of choosing $u_k = \operatorname{argmin}_{u \in \mathcal{U}(i_k)} Q(i_k, u)$. Similarly, with a small probability, the system is forced to move to a random state. This small probability is referred to as the *exploration probability*.

An important advantage of the Q-learning algorithm is that once we construct a good approximation Q , if the system is in state i , then we can simply take the action $\operatorname{argmin}_{u \in \mathcal{U}(i)} Q(i, u)$. In this way, we avoid dealing with transition probability matrices

when choosing an action. However, the Q-learning algorithm still requires storing of an $n \times |\mathcal{U}|$ dimensional approximation, which can be quite large in practical applications. There is a commonly used, albeit a heuristic, variant of the Q-learning algorithm that uses a parameterized approximation architecture similar to that in Equation (6). Letting $\tilde{Q}(i, u, r)$ be an approximation to $Q^*(i, u)$ parameterized by the L dimensional vector r of adjustable parameters, this variant uses the updating procedure

$$r \leftarrow r + \gamma [g(i_k, u_k, s_k) + \alpha \min_{v \in \mathcal{U}(s_k)} \tilde{Q}(s_k, v, r) - \tilde{Q}(i_k, u_k, r)] \nabla_r \tilde{Q}(i_k, u_k, r) \quad (12)$$

to tune the adjustable parameters. Bertsekas and Tsitsiklis [1] provide a heuristic justification for the updating procedure in Equation (12). In Equation (11), if we have $g(i_k, u_k, s_k) + \alpha \min_{v \in \mathcal{U}(s_k)} Q(s_k, v) \geq Q(i_k, u_k)$, then we increase the value of $Q(i_k, u_k)$. Similarly, in Equation (12), if we have $g(i_k, u_k, s_k) + \alpha \min_{v \in \mathcal{U}(s_k)} \tilde{Q}(s_k, v, r) \geq \tilde{Q}(i_k, u_k, r)$, then we would like to increase the value of $\tilde{Q}(i_k, u_k, r)$, but we can change the value of $\tilde{Q}(i_k, u_k, r)$ only by changing the adjustable parameters r . In Equation (12), if we have $g(i_k, u_k, s_k) + \alpha \min_{v \in \mathcal{U}(s_k)} \tilde{Q}(s_k, v, r) \geq \tilde{Q}(i_k, u_k, r)$ and the ℓ th component of $\nabla_r \tilde{Q}(i_k, u_k, r)$ is nonnegative so that $\tilde{Q}(i_k, u_k, r)$ is an increasing function of r_ℓ , then we increase the ℓ th component of r . The hope is that this changes the ℓ th component of r in the right direction so that $\tilde{Q}(i_k, u_k, r)$ also increases. Of course, this is not guaranteed in general since all of the components of r change simultaneously in the updating procedure in Equation (11). As a result, the updating procedure largely remains a heuristic.

The Q-learning algorithm was proposed by Watkins [20] and Watkins and Dayan [21]. Sutton and Barto [2], Si *et al.* [3] and Barto *et al.* [22] give comprehensive overviews of the research revolving around the Q-learning algorithm. Bertsekas and Tsitsiklis [1] and Tsitsiklis [23] show that the Q-learning algorithm fits within the general framework of stochastic approximation methods and provide convergence results by building on and extending the

standard stochastic approximation theory. The updating procedure in Equation (11) has convergence properties, but that in Equation (12) with a parameterized approximation architecture is a heuristic. Bertsekas and Tsitsiklis [1] indicate that the updating procedure in Equation (12) has convergence properties when the approximation architecture corresponds to state aggregation, where the entire set of state action pairs is partitioned into L subsets $\{\mathcal{X}_\ell : \ell = 1, \dots, L\}$ and the feature functions in the approximation architecture $\hat{Q}(i, u, r) = \sum_{\ell=1}^L r_\ell \phi_\ell(i, u)$ satisfy $\phi_\ell(i, u) = 1$ whenever $(i, u) \in \mathcal{X}_\ell$ and $\phi_\ell(i, u) = 0$ otherwise. Furthermore, they note that the updating procedure in Equation (12) is also convergent for certain optimal stopping problems. Tsitsiklis and Van Roy [24] apply the Q-learning algorithm to optimal stopping problems arising from the option pricing setting. Kunnumkal and Topaloglu [25,26] use projections within the Q-learning algorithm to exploit the known structural properties of the value function so as to improve the empirical convergence rate. The projections used by Kunnumkal and Topaloglu [25] are with respect to the L -2 norm and they can be computed as solutions to least squares regression problems. The authors exploit the fact that solutions to least squares regression problems can be computed fairly easily and one can even come up with explicit expressions for the same.

LINEAR PROGRAMMING APPROACH

Letting $\{\theta(i) : i \in \mathcal{S}\}$ be an arbitrary set of strictly positive scalars that add up to $1 - \alpha$, the solution to the optimality equation (1) can be found by solving the linear program

$$\max \sum_{i \in \mathcal{S}} \theta(i) J(i) \quad (13)$$

$$\begin{aligned} \text{subject to } J(i) - \sum_{j \in \mathcal{S}} \alpha p_{ij}(u) J(j) \\ \leq \sum_{j \in \mathcal{S}} p_{ij}(u) g(i, u, j) \\ i \in \mathcal{S}, \tilde{u} \in \mathcal{U}(i), \end{aligned} \quad (14)$$

where the decision variables are $J = \{J(i) : i \in \mathcal{S}\}$. To see this, we note that a feasible solution J to the linear program satisfies $J(i) \leq \min_{u \in \mathcal{U}(i)} \{\sum_{j \in \mathcal{S}} p_{ij}(u) [g(i, u, j) + \alpha J(j)]\}$ for all $i \in \mathcal{S}$ so that we have $J \leq TJ$. It is a standard result in the Markov decision process literature that the operator T is monotone in the sense that if $J \leq J'$, then $TJ \leq TJ'$. Therefore, we obtain $J \leq TJ \leq T^2 J$ for any feasible solution J , where the last inequality follows by noting that $J \leq TJ$ and applying the operator T on both sides of the inequality. Continuing in this fashion, we obtain $J \leq T^k J$ for any $k = 0, 1, \dots$. In this case, letting J^* be the solution to the optimality equation (1), since the value iteration algorithm implies that $\lim_{k \rightarrow \infty} T^k J = J^*$, we obtain $J \leq J^*$ for any feasible solution J to the linear program, which yields $\sum_{i \in \mathcal{S}} \theta(i) J(i) \leq \sum_{i \in \mathcal{S}} \theta(i) J^*(i)$. Therefore, $\sum_{i \in \mathcal{S}} \theta(i) J^*(i)$ is an upper bound on the optimal objective value of the linear program. We can check that J^* is a feasible solution to the linear program, in which case, J^* should also be the optimal solution. Associating the dual multipliers $\{x(i, u) : i \in \mathcal{S}, \tilde{u} \in \mathcal{U}(i)\}$ with the constraints, the dual of the linear program is

$$\min \sum_{i \in \mathcal{S}} \sum_{u \in \mathcal{U}(i)} \sum_{j \in \mathcal{S}} p_{ij}(u) g(i, u, j) x(i, u) \quad (15)$$

$$\begin{aligned} \text{subject to } \sum_{u \in \mathcal{U}(i)} x(i, u) - \sum_{j \in \mathcal{S}} \sum_{u \in \mathcal{U}(j)} \alpha p_{ji}(u) x(j, u) &= \theta(i) \\ i &\in \mathcal{S} \end{aligned} \quad (16)$$

$$x(i, u) \geq 0 \quad i \in \mathcal{S}, \tilde{u} \in \mathcal{U}(i). \quad (17)$$

In problem (15)–(17), the decision variable $x(i, u)$ is interpreted as the stationary probability that we are in state i and take action u . In particular, if we add the first set of constraints over all $i \in \mathcal{S}$ and note that $\sum_{i \in \mathcal{S}} p_{ji}(u) = 1$ and $\sum_{i \in \mathcal{S}} \theta(i) = 1 - \alpha$, we obtain $\sum_{i \in \mathcal{S}} \sum_{u \in \mathcal{U}(i)} x(i, u) = 1$ so that $x = \{x(i, u) : i \in \mathcal{S}, \tilde{u} \in \mathcal{U}(i)\}$ can indeed be interpreted as probabilities. If we let (J^*, x^*) be an optimal primal dual solution pair to problems (13)–(14) and (15)–(17), then by the discussion above, J^* is the solution to the optimality equation (1). Furthermore, if

$x^*(i, u) > 0$, then we obtain

$$\begin{aligned} \min_{v \in \mathcal{U}(i)} \left\{ \sum_{j \in S} p_{ij}(v) [g(i, v, j) + \alpha J^*(j)] \right\} \\ = J^*(i) = \sum_{j \in S} p_{ij}(u) [g(i, u, j) + \alpha J^*(j)], \end{aligned}$$

where the second equality follows from the complementary slackness condition for the constraint in problem (13)–(14) that corresponds to $x(i, u)$ and the fact that $x^*(i, u) > 0$. Therefore, if we have $x^*(i, u) > 0$ in the optimal solution to the problem (15)–(17), then it is optimal to take action u whenever the system is in state i .

Problem (13)–(14) has n decision variables and $n \times |\mathcal{U}|$ constraints, which can both be very large for practical applications. One way to overcome the difficulty associated with the large number of decision variables is to use a parameterized approximation architecture as in Equation (6). To choose the adjustable parameters $\{r_\ell : \ell = 1, \dots, L\}$ in the approximation architecture, we plug $\sum_{\ell=1}^L r_\ell \phi_\ell(i)$ for $J(i)$ in problem (13)–(14) and solve the linear program

$$\begin{aligned} \max \quad & \sum_{i \in S} \sum_{\ell=1}^L \theta(i) r_\ell \phi_\ell(i) \quad (18) \\ \text{subject to} \quad & \sum_{\ell=1}^L r_\ell \phi_\ell(i) \\ & - \sum_{j \in S} \sum_{\ell=1}^L \alpha p_{ij}(u) r_\ell \phi_\ell(j) \\ & \leq \sum_{j \in S} p_{ij}(u) g(i, u, j) \\ & i \in S, \forall u \in \mathcal{U}(i), \quad (19) \end{aligned}$$

where the decision variables are $r = \{r_\ell : \ell = 1, \dots, L\}$. The number of decision variables in problem (18)–(19) are L , which can be manageable, but the number of constraints is still $n \times |\mathcal{U}|$. In certain cases, it may be possible to solve the dual of problem (18)–(19) by using column generation, but this requires a lot of structure in the column generation subproblems. One other approach is to randomly sample some state action pairs and include

the constraints only for the sampled state action pairs.

An important feature of problem (18)–(19) is that it naturally provides a lower bound on the optimal discounted cost. In particular, if r^* is an optimal solution to the problem (18)–(19), then letting $\tilde{J}(i, r^*) = \sum_{\ell=1}^L r_\ell^* \phi_\ell(i)$, we observe that $\{\tilde{J}(i, r^*) : i \in S\}$ is a feasible solution to the problem (13)–(14), in which case, the discussion at the beginning of this section implies that $\tilde{J}(\cdot, r^*) \leq J^*$. Such lower bounds on the optimal discounted cost can be useful when we try to get a feel for the optimality gap of a heuristic policy. On the other hand, an undesirable aspect of the approximation strategy in problem (18)–(19) is that the quality of the approximation that we obtain from this problem can depend on the choice of $\theta = \{\theta(i) : i \in S\}$. We emphasize that this is in contrast to problem (13)–(14), which computes the optimal discounted cost for an arbitrary choice of θ . The paper of de Farias and Weber [27] investigates the important question of how to choose θ . However, work is needed in this area. Letting $\tilde{J}(\cdot, r) = \sum_{\ell=1}^L r_\ell \phi_\ell(\cdot)$ and using $\|\cdot\|_\theta$ to denote the θ weighted L_1 norm on $\mathbb{R}^n$, de Farias and Van Roy [28] show that the problem (18)–(19) computes an r that minimizes the error $\|J^* - \tilde{J}(\cdot, r)\|_\theta$ subject to the constraint that $\tilde{J}(\cdot, r) \leq T\tilde{J}(\cdot, r)$. This result suggests that we should use larger values of $\theta(i)$ for the states at which we want to approximate the value function more accurately. These states may correspond to those that we visit frequently or those that have serious cost implications. For this reason, $\{\theta(i) : i \in S\}$ are referred to as the *state relevance weights*. One common idea for choosing the state relevance weights is to simulate the trajectory of a reasonable policy and choose the state relevance weights as the frequency with which we visit different states. There are also some approximation guarantees for problem (18)–(19). Letting r^* be an optimal solution to this problem, de Farias and Van Roy [28] show that

$$\|J^* - \tilde{J}(\cdot, r^*)\|_\theta \leq \frac{2}{1 - \alpha} \min_r \|J^* - \tilde{J}(\cdot, r)\|_\infty. \quad (20)$$

The left side above is the error in the value function approximation provided by problem (18)–(19), whereas the right side above is the smallest error possible in the value function approximation if we were allowed to use any value for r . The right side can be viewed as the power of the parameterized approximation architecture in Equation (6). Therefore, Equation (20) shows that if our approximation architecture is powerful, then we expect problem (18)–(19) to return a good value function approximation.

The linear programming approach for constructing value function approximations was proposed by Schweitzer and Seidmann [29] and it has seen revived interest with the work of de Farias and Van Roy [28]. Noting that the right side of Equation (20) measures the distance between J^* and $\tilde{J}(\cdot, r)$ according to the max norm and it can be quite large in practice, de Farias and Van Roy [28] provide refinements on this approximation guarantee. Since the number of constraints in problem (18)–(19) can be large, de Farias and Van Roy [30] study the effectiveness of randomly sampling some of the constraints to approximately solve this problem. Adelman and Mersereau [31] compare the linear programming approach to other value function approximation methods. Desai *et al.* [32] observe that relaxing constraints (19) may actually improve the quality of the approximation and they propose relaxing these constraints subject to a budget on the total relaxation amount. The work by de Farias and Van Roy [33,34] extends the linear programming approach to average cost criterion. Adelman [35] and Veatch and Walker [36] give examples in the revenue management and queueing control settings, where the column generation subproblem for the dual of problem (18)–(19) becomes tractable.

APPROXIMATE POLICY ITERATION

In practice, both steps of the policy iteration algorithm in the section titled “Notation and Problem Setup” can be problematic. In the policy evaluation step, we need to compute the discounted cost incurred by a policy π , potentially by solving the system of linear

equations $J = T_\pi J$ for $J \in \mathbb{R}^n$. In the policy improvement step, we need to find a policy π that satisfies $TJ = T_\pi J$ for a given vector $J \in \mathbb{R}^n$. Carrying out these two steps exactly is almost never tractable, as it requires dealing with large dimensional matrices.

It is possible to use regression and simulation methods, along with parameterized approximation architectures as in Equation (6), to approximately carry out the policy iteration algorithm. In the approximate version of the policy evaluation step, letting π^k be the policy that we need to evaluate, we generate a sequence of states $\{i_0, i_1, \dots\}$ by following policy π^k . If we let $C_l = \sum_{t=l}^{\infty} \alpha^{t-l} g(i_t, \pi^k(i_t), i_{t+1})$ for all $l = 0, 1, \dots$, then C_l provides a sample of the discounted cost incurred by policy π^k given that we start in state i_l . Therefore, letting r^k be the solution to the regression problem

$$\begin{aligned} \min_r \left\{ \sum_{l=0}^{\infty} [\tilde{J}(i_l, r) - C_l]^2 \right\} \\ = \min_r \left\{ \sum_{l=0}^{\infty} \left[\sum_{\ell=1}^L r_\ell \phi_\ell(i_l) - C_l \right]^2 \right\}, \quad (21) \end{aligned}$$

we can use $\tilde{J}(\cdot, r^k)$ as an approximation to the discounted cost J^{π^k} incurred by policy π^k . In the policy improvement step, on the other hand, we need to find a policy π^{k+1} such that $\pi^{k+1}(i)$ is the optimal solution to the problem $\min_{u \in \mathcal{U}(i)} \{ \sum_{j \in \mathcal{S}} p_{ij}(u) [g(i, u, j) + \alpha J^{\pi^k}(j)] \}$ for all $i \in \mathcal{S}$. In the approximate version of the policy improvement step, we let policy π^{k+1} be such that $\pi^{k+1}(i)$ is the optimal solution to the problem $\min_{u \in \mathcal{U}(i)} \{ \sum_{j \in \mathcal{S}} p_{ij}(u) [g(i, u, j) + \alpha \tilde{J}(j, r^k)] \}$ for all $i \in \mathcal{S}$. If the expectation inside the curly brackets cannot be computed exactly, then we resort to simulation. We note that J^{π^k} used in the policy improvement step of the policy iteration algorithm corresponds to the discounted cost incurred by policy π^k , whereas $\tilde{J}(\cdot, r^k)$ used in the policy improvement step of the approximate policy iteration algorithm does not necessarily correspond to the discounted cost incurred by policy π^k . It is also worthwhile to point out that since we need the action taken by policy π^k when generating the sequence of states $\{i_0, i_1, \dots\}$,

we do not have to compute the action taken by policy π^k in every possible state. We can simply compute the action taken by policy π^k as needed when generating the sequence of states $\{i_0, i_1, \dots\}$.

There is some theoretical justification for the approximate policy iteration algorithm. We observe that there are two potential sources of error in the algorithm. First, the regression in the policy evaluation step may not accurately capture the discounted cost incurred by policy π^k . We assume that this error is bounded by ϵ in the sense that $|\tilde{J}(i, r^k) - J^{\pi^k}(i)| \leq \epsilon$ for all $i \in \mathcal{S}$ and $k = 0, 1, \dots$. Second, we may not exactly compute the action taken by policy π^{k+1} in the policy improvement step. This is especially the case when we use simulation to estimate the expectations. We assume that this error is bounded by δ in the sense that $|[T_{\pi^{k+1}}\tilde{J}(\cdot, r^k)](i) - [T\tilde{J}(\cdot, r^k)](i)| \leq \delta$ for all $i \in \mathcal{S}$ and $k = 0, 1, \dots$, where we use $[T_{\pi^{k+1}}\tilde{J}(\cdot, r^k)](i)$ and $[T\tilde{J}(\cdot, r^k)](i)$ to denote the i th components of the vectors $T_{\pi^{k+1}}\tilde{J}(\cdot, r^k)$ and $T\tilde{J}(\cdot, r^k)$, respectively. Bertsekas and Tsitsiklis [1] show that the approximate policy iteration algorithm generates a sequence of policies whose optimality gaps are bounded by ϵ and δ . In particular, the sequence of policies $\{\pi^k\}_k$ generated by the approximate policy iteration algorithm satisfy $\limsup_{k \rightarrow \infty} \|J^{\pi^k} - J^*\|_\infty \leq (\delta + 2\alpha\epsilon)/(1 - \alpha)$. This result provides some justification for the approximate policy iteration algorithm, but it is clearly difficult to measure ϵ and δ . If we use simulation to estimate the expectations, then there is always a small probability of incurring a large simulation error and coming up with a uniform bound on the simulation error may also not be possible.

A practical issue that requires clarification within the context of the approximate policy iteration algorithm is that the computation of $\{C_l : l = 0, 1, \dots\}$ and the regression problem in Equation (21) involve infinite sums, which cannot be computed in practice. To address this difficulty, for large finite integers N and M with $M < N$, we can generate a sequence of N states $\{i_0, i_1, \dots, i_N\}$ and compute the discounted cost starting from each one of the states $\{i_0, i_1, \dots, i_{N-M}\}$ until

we reach the final state i_N . This amounts to letting $C_l = \sum_{t=l}^{N-1} \alpha^{t-l} g(i_t, \pi^k(i_t), i_{t+1})$ for $l = 0, 1, \dots, N - M$ and we can use these sampled discounted costs in the regression problem. It is straightforward to check that if we have $l \in \{0, 1, \dots, N - M\}$, then the two sums $\sum_{t=l}^{N-1} \alpha^{t-l} g(i_t, \pi^k(i_t), i_{t+1})$ and $\sum_{t=l}^{\infty} \alpha^{t-l} g(i_t, \pi^k(i_t), i_{t+1})$ differ by at most $\alpha^M \bar{G}/(1 - \alpha)$, where we let $\bar{G} = \max_{i,j \in \mathcal{S}, u \in \mathcal{U}(i)} |g(i, u, j)|$. Therefore, truncating the sequence of states may not create too much error as long as M is large.

Bertsekas and Tsitsiklis [1] describe an approximate version of the value iteration algorithm that also uses regression. At any iteration k , this algorithm keeps a vector of adjustable parameters r^k that characterize a value function approximation through the parameterized approximation architecture $\tilde{J}(\cdot, r^k)$ as in Equation (6). We apply the operator T on $\tilde{J}(\cdot, r^k)$ to compute $\{[T\tilde{J}(\cdot, r^k)](i) : i \in \tilde{\mathcal{S}}\}$ for only a small set of representative states $\tilde{\mathcal{S}} \subseteq \mathcal{S}$. The adjustable parameters r^{k+1} at the next iteration are given by the optimal solution to the regression problem $\min_r \sum_{i \in \tilde{\mathcal{S}}} [\tilde{J}(i, r) - [T\tilde{J}(\cdot, r^k)](i)]^2$. Bertsekas and Tsitsiklis [1] give performance bounds for this approximate value iteration algorithm. They indicate that one way of selecting the set of representative states $\tilde{\mathcal{S}}$ is to simulate the trajectory of a reasonable policy and focus on the states visited in the simulated trajectory. Noting the definition of the operator T , computing $[T\tilde{J}(\cdot, r^k)](i)$ requires taking an expectation and one can try to approximate this expectation by using simulation, especially when we do not have the data to estimate the transition probability matrices. Approximate value and policy iteration algorithms that we describe in this section are due to Bertsekas and Tsitsiklis [1] and Bertsekas [10]. Tsitsiklis and Van Roy [37] also give an analysis for the approximate value iteration algorithm.

ROLLOUT POLICIES

The idea behind rollout policies is to build on a given policy and improve the performance

of this policy with reasonable amount of work. For a given policy π with discounted cost J^π , we define policy π' such that $\pi'(i)$ is the optimal solution to the problem $\min_{u \in \mathcal{U}(i)} \{\sum_{j \in \mathcal{S}} p_{ij}(u)[g(i, u, j) + \alpha J^\pi(j)]\}$ for all $i \in \mathcal{S}$. In this case, we can use elementary properties of the policy iteration algorithm to show that policy π' is at least as good as policy π . In other words, the discounted cost $J^{\pi'}$ incurred by policy π' is no larger than the discounted cost J^π incurred by policy π . To see this result, we observe that the definition of policy π' implies that

$$\begin{aligned} & \sum_{j \in \mathcal{S}} p_{ij}(\pi'(i))[g(i, \pi'(i), j) + \alpha J^\pi(j)] \\ & \leq \sum_{j \in \mathcal{S}} p_{ij}(\pi(i))[g(i, \pi(i), j) + \alpha J^\pi(j)] = J^\pi(i), \end{aligned}$$

for all $i \in \mathcal{S}$, where the equality follows by the fact that J^π is the fixed point of the operator T_π . We write the inequality above as $T_{\pi'} J^\pi \leq J^\pi$. It is a standard result in the Markov decision process literature that the operator $T_{\pi'}$ is monotone and applying this operator on both sides of the last inequality, we obtain $T_{\pi'}^2 J^\pi \leq T_{\pi'} J^\pi \leq J^\pi$. Continuing in this fashion, we have $T_{\pi'}^k J^\pi \leq J^\pi$ for all $k = 0, 1, \dots$. By using the value iteration algorithm under the assumption that the only possible policy is π' , we have $\lim_{k \rightarrow \infty} T_{\pi'}^k J^\pi = J^{\pi'}$. Therefore, the last inequality implies that $J^{\pi'} \leq J^\pi$.

The biggest hurdle in finding the action chosen by policy π' is the necessity to know J^π . If policy π has a simple structure, then it may be possible to compute J^π exactly, but in general, we need to estimate J^π by using simulation. In particular, given that the system is in state i , to be able to find the action chosen by policy π' , we try each action $u \in \mathcal{U}(i)$ one by one. For each action u , we simulate the transition of the system from state i to the next state. From that point on, we follow the actions chosen by policy π . Accumulating the discounted cost incurred along the way yields a sample of $\sum_{j \in \mathcal{S}} p_{ij}(u)[g(i, u, j) + \alpha J^\pi(j)]$. By simulating multiple trajectories, we can use a sample average to estimate

$\sum_{j \in \mathcal{S}} p_{ij}(u)[g(i, u, j) + \alpha J^\pi(j)]$. Once we estimate this quantity for all $u \in \mathcal{U}(i)$, the action that yields the smallest value for $\sum_{j \in \mathcal{S}} p_{ij}(u)[g(i, u, j) + \alpha J^\pi(j)]$ is the action chosen by policy π' when the system is in state i . This approach is naturally subject to simulation error, but it often performs well in practice and it can significantly improve the performance of the original policy π . It is also worthwhile to emphasize that the original policy π can be an arbitrary policy, including policies driven by value function approximations or heuristics.

There are numerous applications of rollout policies, where one can significantly improve the performance of the original policy. Tesauro and Galperin [38] use rollout policies to strengthen several strategies for playing backgammon. Bertsekas *et al.* [39] view certain combinatorial optimization problems as sequential decision processes and improve the performance of several heuristics by using rollout policies. Bertsekas and Castanon [40] provide applications on stochastic scheduling problems and Secomandi [41] focuses on vehicle routing problems. Yan *et al.* [42] generate strategies for playing solitaire by using rollout policies.

STATE AGGREGATION

An intuitive idea to deal with the large number of states is to use state aggregation, where we partition the state space into a number of subsets and assume that the value function is constant over each partition. To this end, we use $\{\mathcal{X}_\ell : \ell = 1, \dots, L\}$ to denote the partition of the states such that $\cup_{\ell=1}^L \mathcal{X}_\ell = \mathcal{S}$ and $\mathcal{X}_\ell \cap \mathcal{X}_{\ell'} = \emptyset$ for all $\ell \neq \ell'$. We assign the value r_ℓ to the value function over the partition $\mathcal{X}_\ell$. The interesting question is whether we can develop an algorithm that finds a good set of values for $\{r_\ell : \ell = 1, \dots, L\}$. Using $\mathbf{1}(\cdot)$ to denote the indicator function, one approach is to generate a sequence of states $\{i_0, i_1, \dots\}$ so that if we have $i_k \in \mathcal{X}_\ell$, then we update r_ℓ by using the stochastic approximation iteration

$$\begin{aligned}
r_\ell &\leftarrow (1 - \gamma)r_\ell \\
&+ \gamma \min_{u \in \mathcal{U}(i_k)} \sum_{j \in S} p_{ij}(u) \\
&\left[g(i_k, u, j) + \alpha \sum_{l=1}^L \mathbf{1}(j \in \mathcal{X}_l) r_l \right] \quad (22)
\end{aligned}$$

immediately after observing state i_k . One can develop convergence results for the updating procedure in Equation (22) under fairly general assumptions on how the sequence of states $\{i_0, i_1, \dots\}$ are sampled. For example, Bertsekas and Tsitsiklis [1] sample a subset $\mathcal{X}_\ell$ uniformly over $\{\mathcal{X}_\ell : \ell = 1, \dots, L\}$. Given that the subset $\mathcal{X}_\ell$ is sampled, they sample $i_k \in \mathcal{X}_\ell$ according to the probabilities $\{q_\ell(i) : i \in \mathcal{X}_\ell\}$. The probabilities $\{q_\ell(i) : i \in \mathcal{X}_\ell\}$ can be arbitrary except for the fact that they add up to one.

We can expect state aggregation to work well as long as the value function is relatively constant within each of the subsets $\{\mathcal{X}_\ell : \ell = 1, \dots, L\}$. We let $\epsilon_\ell = \max_{i, j \in \mathcal{X}_\ell} |J^*(i) - J^*(j)|$ to capture how much the value function fluctuates within the subset $\mathcal{X}_\ell$. In this case, letting $\epsilon = \max_{\ell=1, \dots, L} \epsilon_\ell$, Tsitsiklis [1] show that the updating procedure in Equation (22) converges to a point $\hat{r} = \{\hat{r}_\ell : \ell = 1, \dots, L\}$ that satisfies $|J^*(i) - \hat{r}_\ell| \leq \epsilon/(1 - \alpha)$ for all $i \in \mathcal{X}_\ell$ and $\ell = 1, \dots, L$. Therefore, we estimate the value function with an approximation error of $\epsilon/(1 - \alpha)$. We note that the limiting point of the updating procedure can depend on the choice of the probabilities $\{q_\ell(i) : i \in \mathcal{X}_\ell\}$, but the choice of these probabilities ultimately does not affect the convergence result and the fact that the limiting point provides an approximation error of $\epsilon/(1 - \alpha)$.

We note that a parameterized approximation architecture such as that in Equation (6) is actually adequate to represent state aggregation. In particular, we can define the feature functions $\{\phi_\ell(\cdot) : \ell = 1, \dots, L\}$ such that $\phi_\ell(i) = 1$ whenever $i \in \mathcal{X}_\ell$ and $\phi_\ell(i) = 0$ otherwise. In this case, the adjustable parameter r_ℓ in the parameterized approximation architecture $\sum_{\ell=1}^L r_\ell \phi_\ell(\cdot)$ captures the value assigned to the value function over

the partition $\mathcal{X}_\ell$. Bean *et al.* [43] analyze state aggregation for shortest path problems. Tsitsiklis and Van Roy [37] and Van Roy [44] provide convergence results for updating procedures similar to that in Equation (22). Singh *et al.* [45] pursue the idea of soft state aggregation, where each state belongs to a subset $\mathcal{X}_\ell$ with a particular probability.

CONCLUSIONS

In this article, we have described a number of approaches for alleviating the computational difficulties associated with dynamic programming. Methods such as the temporal difference learning and Q-learning algorithm avoid transition probability matrices by using simulated trajectories of the system to estimate expectations. There are variants of these methods that use parameterized approximation architectures and the goal of these variants is to address the difficulty associated with storing the value function. The linear programming approach solves a large linear program to fit a parameterized approximation architecture to the value function. Approximate policy iteration uses a combination of regression and simulation in an effort to obtain a sequence of policies that improve on each other. Rollout policies start with an arbitrary policy and improve the performance of this policy with relatively small amount of work. State aggregation builds on the intuitive notion of partitioning the state space into a number of subsets and assuming that the value function is constant over each partition.

Owing to the introductory nature of this article and the limited space, our coverage of computational dynamic programming approaches has not been exhaustive. One important point is that if we have a good approximation $\tilde{J}(\cdot, r)$ to the value function, then to be able to make the decisions by using this value function approximation, we need to plug the value function approximation in the right side of the optimality equation (1) and solve the resulting optimization problem. If the number of admissible actions in each state is small, then we can solve the

resulting optimization problem by checking the objective function value provided by each action one by one, but this approach becomes problematic when the number of admissible actions is large. In problems where the action is itself a high dimensional vector, it may be possible to choose the feature functions $\{\phi_\ell(\cdot) : \ell = 1, \dots, L\}$ such that the optimization problem in question decomposes by each component of the action vector. Another way to deal with the resulting optimization problem is to choose the feature functions such that the value function approximation $\tilde{J}(\cdot, r) = \sum_{\ell=1}^L r_\ell \phi_\ell(\cdot)$ ends up having a special structure and the resulting optimization problem can be solved by using standard optimization tools. For example, if the state and the action take values in the Euclidean space, then we may use linear or piecewise linear functions of the state as the feature functions and it may be possible to solve the resulting optimization problem by using linear or integer programming tools. Godfrey and Powell [46,47], Topaloglu and Powell [48], Schenk and Klabjan [49], and Simao *et al.* [50] use linear and piecewise linear value function approximations in numerous dynamic programs that arise from the freight transportation setting. By using such value function approximations, they are able to deal with states and actions that are themselves vectors with hundreds of dimensions.

If the state and the action take values in the Euclidean space, then another useful approach is to decompose the Markov decision problem in such a way that one can obtain approximations to the value function by concentrating on each component of the state separately. Adelman and Mersereau [31] use the term *weakly coupled dynamic program* to refer to dynamic programs that would decompose if a few linking constraints did not couple the decisions acting on different components of the vector valued state. They use Lagrangian relaxation to relax these complicating constraints. They propose methods to choose a good set of Lagrange multipliers and show that their Lagrangian relaxation idea provides lower bounds on the value function. Karmarkar [51], Cheung and Powell [52], Castanon [53] and Topaloglu

[54] apply Lagrangian relaxation to dynamic programs arising from the inventory allocation, fleet management, sensor management, and revenue management settings.

Our development in this article assumes that the feature functions $\{\phi_\ell(\cdot) : \ell = 1, \dots, L\}$ are fixed and $\{\phi_\ell(i) : \ell = 1, \dots, L\}$ are able to capture the important features of state i from the perspective of estimating the discounted cost starting from this state. The construction of the feature functions is traditionally left to the model builder and this task may require quite a bit of insight into the problem at hand and a considerable amount of trial and error. There is some recent work on developing automated algorithms to construct the feature functions and this is an area that can be beneficial to all of the methods that we described in this article. Klabjan and Adelman [55] use a special class of piecewise linear functions as possible candidates for the feature functions. They show that it is possible to approximate any function with arbitrary precision by using enough number of functions from their special class. Veatch [56] considers control problems in the queueing network setting and describes an approach for iteratively adding feature functions from a predefined set.

COMPUTATIONAL BIOLOGY AND BIOINFORMATICS: APPLICATIONS IN OPERATIONS RESEARCH

THE INTERPLAY BETWEEN OPERATIONS RESEARCH AND THE LIFE SCIENCES

Operations research (OR) was a young discipline in the 1950s when it had its first brush with the biological sciences. For instance, initial computer simulations of evolution were conducted by Barricelli in the middle 1950s [1], and in the 1960s, Bremermann described how genetic algorithms could be used to solve optimization problems [2]. A more modern example of how the biological sciences have impacted our ability to heuristically search for optimality is that of ant colony optimization, which was developed in the 1990s [3]. OR's overarching goal to improve, and if possible optimize, the decision-making process has benefited from mimicking natural processes as nature itself seems to seek optimality.

While OR has adopted biological principles for its own advancement, the intrinsic disciplinary overlap suggests that the biological sciences might similarly benefit from OR. Indeed, the innate optimal quality of nature, together with the fact that OR has built a myriad of mathematical and computational methods to compute optimal quantities, has promoted the application of OR to problems in the biological sciences. Biological applications of OR tend to differ from OR applications in business and industry because the biological entities are not independent agents that can make decisions. Even so, the natural trends of many biological entities

are often toward optimal states that can be appropriately modeled with traditional OR techniques.

The application of OR to biology blossomed with the advent of the fields of computational biology and bioinformatics in the 1990s. Numerous biological investigations were moving from wet lab research to computer models that could simulate a natural process. The computational setting promised a vast increase in the speed of our experimental ability, and hence, the number of (simulated) experiments could be far larger than what would have been possible in a laboratory. Simulated results could then be used to identify which experiments should be confirmed by more costly wet lab research.

This article samples some of the OR applications in the biological sciences. The presentation is arranged relative to biological scale, starting with problems in biochemistry and moving toward legacy studies of entire populations. Other surveys of OR applications in biology are divided by the type of OR [4]. Each section below begins with a succinct introduction describing the biological relevance and ends with OR examples. Further details are found in the citations.

PROTEINS

Proteins are the functional workhorses of life. For example, proteins form the contractile elements in muscle tissue as well as the walls of the ion channels in the neurons controlling those muscles. Mammary acinar cells create the large amounts of protein in breast milk while simultaneously responding to protein signaling molecules in their environment. Proteins on the surfaces of some viruses act as syringes for injecting DNA into host cells. Other proteins span the cell walls of bacteria and combine to form molecular motors. Protein tethers and anchors pull chromosomes apart during cell division, and synthetic proteins can mark other proteins on

the surface of cancerous cells so that cytotoxins, made of protein, can kill those cancerous cells without harming healthy ones. There are proteins that allow immune cells to recognize and respond to pathogens, and there are proteins (prions) that are themselves inanimate pathogens.

Biological Introduction

Proteins in their simplest form are bonded chains of amino acid molecules. These polypeptide chains can be composed of tens of thousands of the many known types of amino acids (20 in humans), allowing staggering combinatorial complexity. The amino acid sequence of a peptide chain is known as the protein's *primary structure*.

The importance of proteins and their amino acid building blocks is illustrated by the theory that all life on the Earth started with the formation of amino acids. In 1953 Miller, under the supervision of Urey, placed water, methane, ammonia, and hydrogen into a vessel and applied heat and electricity [5]. Trace amounts of amino acids were identified 2 weeks later. In 1969, the Murchison meteorite struck Australia, and when examined, it was found to contain amino acids. More recently, amino acids were discovered in lunar soil from the Apollo missions [6]. It is tempting to interpret the genesis and apparent ubiquity of amino acids as the fascinating origins of life on the Earth; however, the primary structure only initiates the protein story.

Amino acids within a single peptide chain can form weak bonds with others nearby, leading to *secondary structures* such as α helices, β sheets, and β barrels. Secondary structures create relatively rigid and geometrically fixed regions on an otherwise flexible chain. Because these structures may form in multiple locations along the chain, combinatorial complexity beyond that of the primary sequence is possible.

Stronger bonds between distant amino acids can form either spontaneously or with the assistance of chaperon proteins. These bonds cause proteins to fold and become compact and globular, with some amino acids being internalized. This *tertiary structure* is the basis of protein function. Folding can,

in theory, be modeled by simulating molecular dynamics or quantum mechanics. However, such simulations are complicated by the action of small molecules and other proteins, which may interfere or assist with folding. A stable fold is assumed to represent a locally optimal energetic state, but other local optima may exist, and a protein may oscillate among multiple folded states. These temporal dynamics augment the spatial combinatorial complexity.

Quaternary structures are formed by multiple polypeptide chains, further increasing complexity and potential functionality. An example is that of the potassium ion channel embedded in a neuron's cell membrane. The ion channel is formed by four total protein subunits of two types, each of which can be in an open or closed state.

OR Applications and Proteins

Arguably the biggest outstanding problem in computational biology is the simulation of protein folding. The ability to accurately predict tertiary structure from primary sequence, and hence, the ability to infer functionality from amino acid chains, would revolutionize much of biology, medicine, and health care. However, this proverbial "holy grail" of computational biology has eluded our scientific and computational abilities. From an OR perspective, protein folding is a difficult nonlinear, global optimization problem that minimizes free energy. The free energy model is based on the pioneering work of Christian Anfinsen [7], which leads to the thermodynamic hypothesis stating that a protein's native state is uniquely determined by its primary sequence. There are several introductions to protein folding, see Refs [8–10] as examples.

Each amino acid is uniquely determined by a side-chain of atoms, and the torsion angle of the bond that connects a side-chain to the protein is called a *rotamer*. Only a few choices for each rotamer are possible owing to energy restrictions. The possible angles at each site are cataloged in a library. Determining side-chain conformations to minimize energy is called the *rotamer assignment problem*, which has traditionally been a nonlinear

combinatorial problem [11] (see Ref. [12] for related semidefinite optimization).

Another problem in which OR can help is the searching, comparing, and cataloging of proteins whose structures are stored in a database. The protein data bank, <http://www.rcsb.org>, collects and stores protein structures, and as of 2013, the database was nearing 100,000 structures. Traditional comparisons among proteins were made by aligning amino acid sequences, but the goal of identifying functional similarity is better addressed by aligning three dimensional folds. However, conducting all pairwise comparisons requires efficient algorithms and clever modeling. Several combinatorial approaches in the early 2000s were suggested, see Refs [13] and [14]. Such combinatorial approaches required days of computing to complete the pairwise comparisons of small, 40 protein databases, and their ability to identify known protein families was imperfect. A few years later, several groups realized how to use dynamic programming to efficiently and accurately align larger databases [15–17], and databases with 100s of proteins can now be solved in seconds with perfect accuracy. The increased efficacy has further led to stochastic studies [18].

METABOLISMS

High throughput biological experiments have produced an immense amount of information about cellular processes, and whole-cell models based on this data are becoming possible. The grand goal is to build computational models that couple gene expression and protein interaction with the metabolism. This three tiered approach to whole-cell modeling mirrors the central dogma of molecular biology, which asserts a one-way flow of information from DNA to mRNA to protein, and while imperfect, the central dogma remains the prevailing framework with which to approach cellular biology. The first tier is a network that explains the co-expression of the genes encoded by the DNA, and the second tier is a network that explains pairwise relationships between the resulting proteins. The last tier is the metabolism, which is the collection

of biochemical reactions that supports life. Linking the three networks so that they correctly imitate the regulatory and reactive mechanisms of a cell is a research question on which OR can have an impact. Indeed, standard OR tools have already established themselves substantively in the study of metabolisms as discussed below.

Biological Introduction

A cell's metabolism is the net flux of all biochemicals in and out of the cell. Cells intake carbohydrates, proteins, lipids, and many small molecules and ions. These species act as building materials and fuel for the cell as it grows, repairs itself, recycles molecules, replicates its genome, and exports materials to its environment.

The engines driving these microscopic metabolic factories are the mitochondria. These organelles convert the energy held in the bonds of nutrients into readily usable energy that is stored in the bonds of the molecule adenosine triphosphate (ATP). ATP is transported intra- and intercellularly, and it fuels the metabolism by sequentially breaking off phosphate groups to extract energy, which transforms ATP into diphosphate and monophosphate forms [ADP (adenosine diphosphate) and AMP (adenosine monophosphate)]. An aerobic metabolism produces ATP from carbohydrates using available oxygen. Energy production in animal cells is primarily aerobic. Anaerobic production of ATP is possible, although less efficient. The primary mechanism of ATP production in yeast is anaerobic, and *Escherichia coli* cells can survive in either an aerobic or anaerobic state.

Different cell types emphasize different metabolic processes and products. Muscle cells create relatively large amounts of ATP to fuel the contraction cycle in muscle fibers. Brain cells create and recycle surface receptors, ion channels, and neurotransmitters. Cells of the liver and gall bladder emphasize the production of enzymes used for digestion. Mammary cells secrete milk lipids and proteins. Amoeba secrete cyclic AMP in order to communicate with neighboring amoeba. Penicillium fungi produce antibiotics to fend off bacterial opportunists, and cells of the

hair follicles intake sulfurous compounds to use in cross-linking proteins to produce thin but durable strands of hair.

Although many components of the cellular metabolism are well characterized, the timing and quantification of a metabolism, especially for ensembles of cells, are poorly understood. A collection of cells can be viewed as a black box. In some well-controlled experiments, all inputs to and outputs from this box can be measured. Broad conclusions can be drawn about the metabolism of a typical cell, but this averaging to quantify a typical cell is deceptive. Intercellular interactions are homogenized over the ensemble, as though a single cell in isolation would be capable of accomplishing all metabolic feats on its own.

OR and Metabolic Models

Mathematical programming has proven itself to be a trusted computational tool in the study of whole-cell metabolisms. Metabolic models are constructed by listing the chemical reactions of the cell to create a stoichiometric matrix, S . The linear system $Sv = 0$ holds if the metabolism is assumed to have evolved to a steady state, where v_j is the flux of reaction j . The resulting system is underdetermined, and an objective function is introduced to help identify reasonable metabolic states. Typically, the objective is the growth rate, although others have been suggested and studied [19]. Allowing $g(v)$ to be an appropriate objective, the flux balance analysis (FBA) model is

$$\max\{g(v) : Sv = 0, L \leq v \leq U\},$$

where L and U are variable bounds on the fluxes.

A common use of FBA is to predict lethal gene knockouts. Removing a gene's expression can remove some of the resulting proteins, which can subsequently halt reactions. In cells such as *E. coli*, the map between gene knockouts and reactions is well understood, and an FBA model can replicate the gene knockout by setting the appropriate fluxes to zero. If the optimal value diminishes sufficiently, then the gene knockout is lethal and the gene is said to be essential. FBA

correctly predicts gene essentiality with over 90% accuracy [20].

FBA has been studied and extended in many ways. A quadratic model that minimizes metabolic adjustment is a common adaptation to predict gene essentiality [21]. Extreme pathways have been studied as basic optimal solutions [22], and the central metabolism can be identified if FBA's innate degeneracy is handled carefully [23]. Robust extensions to accommodate stochastic modeling parameters have also been investigated [24]. Lastly, recent directives suggest amalgamations that meld metabolic models with gene expression to include external factors such as temperature stress [25].

MICROTUBULES

Cells require infrastructure to house their metabolic outcomes much like factories require infrastructure to produce their goods. The functional scaffolding of many cells is formed by microtubules, which are rigid proteinaceous tubes similar in diameter to carbon nanowires and nanotubes. Microtubules endow cells with rigidity, transport organelles, provide cellular locomotion, regulate cell growth and geometry, and separate chromosomes during cell division.

Cells come in numerous shapes, sizes, and forms. For example, a huge ostrich egg is a single cell, as is the nucleus-free red blood cell. Microtubule interactions are responsible for the cellular structure in each case. The regulation of microtubule interactions varies depending on cell type, and computational models that simulate the growth and demise of microtubule structures aid our understanding of the complex structural dynamics.

Biological Introduction

At the start of mitotic cell division in animals, a cell's centrosome is duplicated and the resulting pair separates. The centrosomes migrate to opposite poles of the cell. A centrosome is a hub from which microtubule spokes emanate, and as cell division proceeds, tubules emanating from a centrosome lengthen and attach to chromosome pairs

aligned along the cell's midline. Because the centrosomes are anchored to the plasma membrane, the chromosomal microtubules can contract and pull chromosome pairs toward the poles. Once the centrosomes are symmetrically separated, cell division proceeds, leaving each daughter cell with a full genetic complement and a single centrosome.

Microtubules apply force by altering their length, which varies according to a dynamically unstable biochemical process. Tubulin heterodimers bind sequentially to form a hollow tube with 13 dimers per helical revolution. Because the helix is composed of tubulin heterodimers (a bonded pair of two types of tubulin monomers), the two exposed ends of the microtubule present different monomers. This polarization of the microtubule results in different binding affinities for free tubulin on each end, with the + end binding more readily than the - end. The unstable nature of microtubules allows rapid changes in length.

Microtubules grow by the addition of tubulin dimers and decay by their removal. Guanine triphosphate (GTP) biases the reaction governing the addition of tubulin to the helix, making attachment more probable. The tendency for lengthening and shortening varies with the amount of GTP. Even if GTP concentrations maintain a microtubule's length, a dynamic equilibrium is present in which tubulin dimers are constantly added and removed. In general, microtubules are always undergoing a process called *treadmilling*, meaning that tubulin dimers are continually being added and/or dropped.

Microtubules self-organize into microtubule arrays during plant cell development. These cortical microtubules (CMT) exhibit polarized $\pm$ structure, but this polarization does not result in - ends gathering at a common center. Instead, numerous local interactions between a large population of nearly identical CMTs influence dynamic organization and assembly. CMTs in plants have been observed to assemble into astral structures, bundles, and parallel cross-linked sheets. These dynamic CMT arrays act as scaffolds, directing the placement of structural fibers necessary to the formation

of a new cell wall. Movement and placement of microtubules are governed by interactions within the array as well as by treadmilling. Arrays with tubules transverse to the elongation axis are correlated to continued elongation, while arrays with longitudinal or oblique orientation correlate to the cessation of elongation.

OR and Microtubules

A three-dimensional discrete event simulation of CMT organization is developed in Refs [26] and [27]. This model probabilistically assumes that the + end of the microtubule grows, shrinks, or pauses depending on the length of time that it is in one of these three states. The transition from one state to another is modeled with an exponential distribution, and once a transition has been triggered, the + end enters the next state. The - end is modeled similarly but without the pause state. The rate of growth or decay is sampled from a normal distribution. All probabilistic parameters are tuned to mimic experimental observations.

The outcome of a random interaction between two CMTs is decided by the angle of intersection. If an intersecting CMT forms an angle of less than 40° with another CMT (called the *barrier* CMT of the interaction), then the intersecting CMT aligns with the barrier CMT. If the angle is at least 40° , then 30% of the time the intersecting CMT begins to shorten. The remaining 70% of the time the intersecting CMT passes through the barrier CMT. Intersecting the cell wall always forces the microtubule to enter a shortening phase.

Discrete event simulations are commonly used in OR to study stochastic problems, and it is well known that simple, random decision rules can lead to complex dynamics. In the case of CMT organization, a well-tuned simulation reproduces the complex observable phenomena found in cells. Moreover, the model accurately predicts mutant behavior caused by mutations in the MOR1 and FRA2 genes. The trust built by verifying the computational model's efficacy against experimental results then adds credence to computational queries about how a cell's structure might be affected by altering the interactions.

EPIDEMICS

Infectious diseases have plagued humankind throughout history, and modeling their spread is a stalwart in mathematical and computational biology. Standard OR techniques have not been commonly used, although (stochastic) differential equation models and statistical analyses are routine. Indeed, the 2005 review article [28] states that “No humanitarian emergencies (epidemics, famine, war and genocide) were addressed in the OR/MS related journals.” However, some OR work is emerging, and the magnified public safety importance associated with the spread of disease suggests that OR should be considered as the research community investigates new models. In the following section, we introduce the biology of the spread of disease and then mention where OR has made an appearance.

Biological Introduction

Infectious diseases spread from individual to individual via a transmission vector. Disease vectors include viruses, bacteria, fungi, protozoa, and proteins known as *prions*. The spread of disease can occur from one cell to another, as is the case with replicating viruses in multicellular hosts, or between individuals across vast geographical scales, as is the case with the human immunodeficiency virus (HIV) and the influenza pandemic of 1918.

Transmission vectors can occur horizontally among individuals of the same species, vertically from mother to child during gestation or birth, and from one individual to another of a different species or subspecies. The Norwalk virus exemplifies the former as it famously victimized masses of cruise ship patrons, causing symptoms akin to severe food poisoning [29]. Herpes and HIV are easily transmitted vertically. The bird and swine strains of influenza transmit back and forth between humans and other species, mutating each time [30]. The vector may be detrimental to both species or harmless to one, as is the case with malarial parasites in mosquito serum.

The initiation of spreading pathogens is termed an *outbreak*. An *epidemic* is characterized by affected individuals increasing in number and broadening in geographical locale. During a *pandemic*, the extent of infection reaches a global scale. Entities such as the Center for Disease Control and the World Health Organization analyze quantitative models to aid in detecting and containing outbreak events.

The nature of the pathogen effects its mode of transmission within and between populations. Rhinovirus (the common cold) may spread via handshake, whereas *E. coli* bacteria can wait for hosts on a doorknob or a head of lettuce. A viable fungal spore can blow into an area on the wind or be revived from fossilized amber after millions of years. Giardia protozoa are commonly drunk from wells or ponds after being expelled through the gastrointestinal tract of another species. Prions, an inanimate vector made solely of proteins, with no genetic material, can be spread among species by consuming the brains of the infected.

The spread of an infectious disease may have consequences ranging from undetectable to lethal. Warts, caused by some types of HPV (human papillomavirus), are inconvenient. Common colds may seem innocuous, but they are responsible for roughly \$40 billion of lost productivity and medical expenses each year [31]. Crippling conditions are possible from more severe infections such as polio and tuberculosis or from benign infections such as rubella in immunodeficient individuals. Some pathogens even gain control of the infected host and alter behavior [32].

OR Applications and Epidemics

The first overlap between traditional OR and the modeling of epidemics seems to be the combination of differential equations, queuing theory, and policy analysis to study the spread of smallpox [33, 34]. The intersection with OR is the use of a queue to track the individuals awaiting vaccination as a policy of distribution is employed. From an operational perspective, the model can be used to assess containment policies and to guide implementation. While the use of stochastic

processes to study epidemics has a long history, the model in Ref. [33] and the expertise of the authors is a clear bridge between OR and epidemiology. Other works have followed [35–37]. The review article [37] suggests many research opportunities.

POPULATION RECONSTRUCTION

Mapping the generational progressions of species helps us identify the evolutionary aspects that underlie numerous areas of biology. However, our ability to genetically track whole populations is recent, and in most cases, we have what is essentially a brief snap-shot of a long, long genetic evolution. Inferring previous populations from current genetic information importantly informs evolutionary processes, and OR models have found success in doing so.

Biological Introduction

Population genetic studies provide information about migrations, inheritance, mutation rates, evolution, and speciation. If the DNA sequences of a parent and its offspring are compared so as to locate small genetic alterations, for example, single nucleotide polymorphisms (SNPs or snips), then information about mutation rates from one generation to the next can be gleaned. These parent/offspring mutation rates help explain the long-term evolution of the species. However, sequence comparison between family members is only possible if the family structure is known. In wild populations, observing these familial relationships is often impossible, and the genetic information needs to be analyzed to infer family relationships.

The persistence of a population may be influenced by its ability to relocate, which, for example, enables the population to adapt to changing resources and habitat. Some prehistoric human populations were known to have migrated small distances annually along shorelines to ensure adequate marine food sources. By contrast, the arctic tern boasts the longest known migratory patterns, flying over 2 million kilometers during its 30-year life span. Plant seeds and pollen may also be transported large

distances. Air and sea currents are believed to have relocated many plant species across the Atlantic Ocean. While the geographical range occupied by a species can sometimes be observed, the migratory and dispersal mechanisms by which this range is obtained may remain hidden. Reconstructing familial relationships, possibly many generations back, enables our understanding of how populations evolve. Population reconstruction has facilitated some seed and pollen dispersal studies. Indeed, the reconstruction of family relationships in oak trees made clear that offspring could emerge at surprisingly long distances from the parent [38].

The health of a population is partially determined by its DNA sequence. Knowing the primary sequence of DNA reveals much of an organism's ability to produce proteins. Transcription of particular DNA sequences leads to the expression of particular proteins that enable cells to perform particular functions. However, knowledge of the genome and proteome does not reveal which proteins will be expressed in which cells and at what time. Illuminating the roles of RNA and regulatory proteins has led to deeper understanding of the specificity and timing of gene expression.

Further complicating the gene expression mechanism is the *epigenome*. Portions of DNA bind to *histones*, molecules that cause DNA to coil and cluster into untranscribable *chromatin*. Other molecules can alter the binding properties of histones, remodeling the chromatin and allowing transcription to occur. The quantity and variety of histone-regulating molecules is influenced by an organism's diet, environment, stress levels, and inheritance. Studies of the combined effect of inheritance and diet have revealed that nutrient intake by parents or grandparents can influence epigenetic factors in the offspring. This epigenetic memory is known to have led to the emergence of schizophrenia in offspring conceived during famine times [39]. Reconstructing populations allows deeper analysis of the modes of acquisition and inheritance of epigenetic factors.

OR Applications and Population Reconstruction

Genes are sequences of DNA that code for specific traits, and locations on the genome that distinguish individuals within a taxa are called *SNPs*. A *haplotype* is a collection of SNPs, and a *genotype* is a coupled pair of haplotypes, each of which is donated by the individual's parents. The problem of inferring haplotypes from genotypes is called *haplotyping*. Each SNP of a haplotype can have one of two states, and if the SNPs of the two sides of a genotype agree, then the genotype is homozygous at the location of the SNP. Otherwise the genotype is heterozygous at that location.

In the presence of heterozygous SNPs, the parental donations are unclear, and the problem of inferring haplotypes requires an inference rule. A classic inference rule is that of pure parsimony, which asks to identify a smallest collection of haplotypes that can combine to explain the current generation's genotypes. Another inference rule is that of perfect phylogeny, which requires that the selected haplotypes comply with the structure of a tree to ensure that each haplotype is a copy of one of the parental haplotypes. Phylogenetic design is itself a problem with substantial overlap with OR [40–42].

Both inference rules naturally lead to combinatorial optimization problems that have received attention in the OR community, see Ref. [43] as a review. A related problem is to directly identify siblings and half-siblings from genotypes, which again naturally leads to combinatorial problems that include Mendelian laws of inheritance [44]. These combinatorial methods have become accurate enough to identify flaws in existing datasets [45].

CONCLUSION

Biology and its related disciplines in medicine and health have had an impressive and impactful history. However, whereas common motivation once rested on observation and classification, many of the advances of the last few decades have been fueled by a bonanza of information. The result

is a science that stands on its ability to infer new experiments and outcomes based on our new collective of knowledge. The combination of science, data, modeling, computation, and mathematics is now at the forefront of biological research, and the application of OR is natural and productive. That said, the synergy between OR and biology is challenged by a gulf of differences in language, application, and education. The promise of joint benefit to both biology and OR demands the combined expertise of both disciplines. In the authors' experience, operations researchers, mathematicians, computer scientists, and engineers will find welcoming colleagues in the life sciences. The possibility of intriguing joint research is nearly ensured independent of the particular biological focus, indeed, OR applications already exists over a wide range of biological scale as demonstrated by this brief synopsis.

COMPUTATIONAL METHODS FOR CTMCs

TUĞRUL DAYAR

WILLIAM J. STEWART
Department of Computer Science,
North Carolina State University,
Raleigh, North Carolina

In a *continuous-time Markov chain* (CTMC), a change of state may occur at any point in time. We say that a stochastic process $\{X(t), t \geq 0\}$ is a CTMC if for integers (states) i, j, k and for all time instants s, t, v with $t \geq 0, s \geq 0$, and $0 \leq v \leq s$, we have

$$\begin{aligned} \text{Prob}\{X(s+t) = k | X(s) = j, X(v) = i\} \\ = \text{Prob}\{X(s+t) = k | X(s) = j\}. \end{aligned}$$

Notice from this definition that not only is the sequence of previously visited states irrelevant to the future evolution of the chain, but so too is the amount of time already spent in the current state.

If the CTMC is *nonhomogeneous*, we write

$$p_{ij}(s, t) = \text{Prob}\{X(t) = j | X(s) = i\},$$

where $X(t)$ denotes the state of the Markov chain at time $t \geq s$. On the other hand, when the CTMC is *homogeneous*, these transition probabilities depend on the difference $\tau = t - s$ rather than on the actual values of s and t . In this case, we simplify the notation by writing

$$\begin{aligned} p_{ij}(\tau) &= \text{Prob}\{X(s+\tau) = j | X(s) = i\} \\ &\text{for all } s \geq 0. \end{aligned}$$

This denotes the probability of being in state j after an interval of length τ , given that the current state is state i . It depends on the length τ but not on s , the specific moment at which this time interval begins.

Whereas a discrete-time Markov chain (DTMC) is represented by its matrix of *transition probabilities*, $P(n)$ at time step n , a CTMC is represented by its matrix of *transition rates*, $Q(t)$ at time t . In this article, we restrict our attention to homogeneous CTMCs where the elements of the transition-rate matrix, now written as Q , are given by

$$\begin{aligned} q_{ij} &= \lim_{\Delta t \rightarrow 0} \left(\frac{p_{ij}(\Delta t)}{\Delta t} \right), \quad i \neq j; \\ q_{jj} &= \lim_{\Delta t \rightarrow 0} \left(\frac{p_{jj}(\Delta t) - 1}{\Delta t} \right). \end{aligned}$$

It is apparent from these equations that the diagonal element in each row of Q is equal to the negated sum of the off-diagonal elements in that row and hence the sum of all elements in any row of Q must be zero.

Let $\pi_i(t) = \text{Prob}\{X(t) = i\}$ be the probability that a CTMC is in state i at time t . Then the probability that the CTMC is in state i at time $t + \Delta t$, correct to terms of order $o(\Delta t)$, must be equal to the probability that it is in state i at time t and it does not change state in the period $[t, t + \Delta t)$, plus the probability that it is in some state $k \neq i$ at time t and moves to state i in the interval Δt , that is,

$$\begin{aligned} \pi_i(t + \Delta t) &= \pi_i(t) \left(1 - \sum_{\text{all } j \neq i} q_{ij} \Delta t \right) \\ &\quad + \left(\sum_{\text{all } k \neq i} q_{ki} \pi_k(t) \right) \Delta t + o(\Delta t). \end{aligned}$$

Since $q_{ii} = -\sum_{\text{all } j \neq i} q_{ij}$, we may write

$$\begin{aligned} \lim_{\Delta t \rightarrow 0} \left(\frac{\pi_i(t + \Delta t) - \pi_i(t)}{\Delta t} \right) \\ = \lim_{\Delta t \rightarrow 0} \left(\sum_{\text{all } k} q_{ki} \pi_k(t) + o(\Delta t) / \Delta t \right), \end{aligned}$$

that is,

$$\frac{d\pi_i(t)}{dt} = \sum_{\text{all } k} q_{ki} \pi_k(t).$$

In matrix notation, this gives

$$\frac{d\pi(t)}{dt} = \pi(t)Q.$$

It follows that the solution $\pi(t)$ is given by

$$\pi(t) = \pi(0)e^{Qt} = \pi(0) \left(I + \sum_{k=1}^{\infty} (Qt)^k / k! \right),$$

where e^{Qt} is the *matrix exponential* defined by

$$e^{Qt} = \sum_{k=0}^{\infty} (Qt)^k / k!.$$

It is the computation of this vector $\pi(t)$, the *transient distribution* of the CTMC, that is our primary objective in this article. However, we first make some observations concerning the computation of stationary distributions of CTMCs.

STATIONARY DISTRIBUTIONS OF CTMCs

We define an invariant vector of a homogeneous CTMC with transition-rate matrix Q as any nonzero vector z for which $zQ = 0$. If this system of equations has a solution z which is a probability vector ($z_i \geq 0$ for all i and $\|z\|_1 = 1$), then z is a stationary distribution. If replacement of one of the equations by a normalizing equation causes the coefficient matrix to become nonsingular, then the stationary distribution is unique. This is the case when the CTMC is irreducible and finite.

Furthermore, in a homogeneous CTMC, the i th element of the vector $\pi(t)$ is the probability that the chain is in state i at time t and we have just seen that these state probabilities are governed by the system of differential equations

$$\frac{d\pi(t)}{dt} = \pi(t)Q.$$

If the evolution of the CTMC is such that there arrives a point in time at which the rate of change of the probability distribution vector $\pi(t)$ is zero, then the left-hand side of this equation, $d\pi(t)/dt$, is identically equal to zero. In this case, the system has reached a

limiting distribution, which is written simply as π in order to show that it no longer depends on time t .

When the limiting distribution exists, when all its components are strictly positive, and when it is independent of the initial probability vector $\pi(0)$, then it is unique and is called the *steady-state distribution*, also referred to as the *equilibrium* or *long-run probability vector*; its i th element π_i is the probability of being in state i at statistical equilibrium. For a finite, irreducible CTMC, the limiting distribution always exists and is identical to the stationary distribution of the chain. The steady-state distribution may be obtained by solving the system of linear equations

$$\pi Q = 0 \text{ with } \pi u = 1, \quad (1)$$

where u is a column vector containing 1s. With a DTMC, we saw that the steady-state distribution is obtained from

$$\pi P = \pi \text{ with } \pi u = 1, \quad (2)$$

where P is its stochastic transition probability matrix. Observe that both these equations may be put into the same form. We may write the second, $\pi P = \pi$, as $\pi(P - I) = 0$ thereby putting it into the form of Equation (1). Observe that $(P - I)$ has all the properties of a transition-rate matrix, namely, the off-diagonal elements are nonnegative; row sums are equal to zero and diagonal elements are equal to the negated sum of off-diagonal row elements. On the other hand, we may discretize a CTMC. Writing Equation (1) as

$$\pi(Q\Delta t + I) = \pi \text{ with } \pi u = 1, \quad (3)$$

puts it into the form of Equation (2). In this discretized Markov chain, transitions take place at intervals Δt , Δt being chosen sufficiently small that the probability of two transitions taking place in time Δt is negligible, that is, of order $o(\Delta t)$. One possibility is to take

$$\Delta t \leq \frac{1}{\max_i |q_{i,i}|}.$$

In this case, the matrix $(Q\Delta t + I)$ is stochastic and the stationary probability vector π of

the CTMC obtained from $\pi Q = 0$ is identical to that of the discretized chain, obtained from $\pi(Q\Delta t + I) = \pi$. It now follows that numerical methods designed to compute the stationary distribution of DTMCs may be used to compute the stationary distributions of CTMCs. Since this was the topic of the previous article on computational methods for DTMCs, we shall not pursue this topic further. We simply add a cautionary note: transient solutions of the discretized chain represented by the transition probability matrix $Q\Delta t + I$, are not the same as those of the continuous-time chain, represented by the transition-rate matrix Q , although both do have the same stationary distribution.

Before terminating this section, we consider the problem of computing moments of first passage times from a state to a set of states in CTMCs. Without loss of generality, let us assume that the state space is partitioned as $S = \mathcal{F} \cup \mathcal{T}$, $\mathcal{F} \cap \mathcal{T} = \emptyset$, yielding the block partitioning

$$Q = \begin{pmatrix} Q_{\mathcal{F},\mathcal{F}} & Q_{\mathcal{F},\mathcal{T}} \\ Q_{\mathcal{T},\mathcal{F}} & Q_{\mathcal{T},\mathcal{T}} \end{pmatrix}.$$

As for DTMCs, it is possible to compute moments of first passage times from states in $\mathcal{F}$ to $\mathcal{T}$ using a recurrence. However, the recurrence is much simpler in this case:

$$\begin{aligned} -Q_{\mathcal{F},\mathcal{F}} m^{(i+1)} &= (i+1)m^{(i)} \text{ for } i \geq 0 \text{ with } m^{(0)} \\ &= u. \end{aligned} \quad (4)$$

One needs to factorize $-Q_{\mathcal{F},\mathcal{F}}$ once, compute $m^{(i+1)}$ using $m^{(i)}$ and the factors of $-Q_{\mathcal{F},\mathcal{F}}$. The factorization can be performed using Grassmann-Taksar-Heyman (GTH) as for DTMCs, but this time on the coefficient matrix

$$\begin{pmatrix} -Q_{\mathcal{F},\mathcal{F}} & -Q_{\mathcal{F},\mathcal{T}}u \\ w^T & -w^T u \end{pmatrix}$$

(see article **Computational Methods for DTMCs**).

TRANSIENT DISTRIBUTIONS OF CTMCs

Let $\pi_i(t)$ be the probability that a CTMC having transition-rate matrix Q is in state

i at time t . Then, the *transient probability vector* of the CTMC at time t is given by

$$\pi(t) = \pi(0)e^{Qt}.$$

Transient solution methods can be classified into two, based on computing e^{Qt} explicitly or implicitly. The uniformization method and Krylov subspace methods can follow either approach. Decompositional methods and matrix powering follow the former approach, whereas ordinary differential equation (ODE) solvers follow the latter approach. In the next section we start with uniformization, a very simple method suited for this purpose.

Uniformization

Consider the discretized stochastic transition probability matrix

$$P = I + \frac{1}{\Gamma}Q$$

corresponding to the continuous-time process governed by Q that is embedded in a Poisson process of rate $\Gamma = \max_i |q_{i,i}|$. Then the *uniformization equation* [1] is given by

$$e^{Qt} = P(t) = e^{-\Gamma t} \sum_{k=0}^{\infty} \frac{(\Gamma t)^k}{k!} P^k.$$

The right-hand side of this equation can be terminated, say, at $k = K$, and used to compute an approximation to e^{Qt} as in

$$\tilde{\pi}(t) = \pi(0) \sum_{k=0}^K \frac{(\Gamma t)^k}{k!} P^k.$$

Assuming that the order of P is n and it has nz nonzeros, the method is simple to program with two vectors of length n ; it executes about $K(n + nz)$ flops, and has a known truncation error given by

$$\sum_{k=0}^K \frac{(\Gamma t)^k}{k!} \geq \frac{1 - \epsilon}{e^{-\Gamma t}} \Rightarrow \|\pi(t) - \tilde{\pi}(t)\|_{\infty} \leq \epsilon.$$

Its disadvantage is the need to partition t into time steps and use a smaller ϵ for each subinterval when Γt is large.

Next, we consider a group of methods based on decomposing (i.e., factorizing) the coefficient matrix.

Matrix Decomposition

If Q is *nondefective* (meaning, its number of linearly independent eigenvectors is less than its number of eigenvalues), we may write $SQS^{-1} = \Lambda = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_n\}$, implying

$$e^{Qt} = S^{-1}e^{\Lambda t}S,$$

where $e^{\Lambda t} = \text{diag}\{e^{\lambda_1 t}, e^{\lambda_2 t}, \dots, e^{\lambda_n t}\}$. Hence

$$\pi(t) = \pi(0)S^{-1}e^{\Lambda t}S = \sum_{i=1}^n \alpha_i e^{\lambda_i t} s_i,$$

where the linear coefficients α_i are to be computed from $\alpha S = \pi(0)$ and s_i is the i th row of S . Consequently, the transient solution may be computed very efficiently at any time instant.

When Q is (nearly) defective, one can reduce Q to (quasi-)triangular form $OQO^T = W$ using an orthogonal matrix O (through the *Schur decomposition*). Then

$$e^{Qt} = O^T e^{Wt} O.$$

If the QR algorithm of Francis [2,3] is used to compute the Schur decomposition, we have

$$RW = \Lambda R,$$

where R is a triangular matrix, Λ is a diagonal matrix with the eigenvalues, and V is a matrix of left-hand eigenvectors ($V = RO$). Since $Q = O^T R^{-1} \Lambda RO$, we have $\pi(t) = \pi(0)O^T R^{-1} e^{\Lambda t} RO$. Then one can solve $\alpha R = \pi(0)O^T$ for α and compute $\pi(t) = \alpha e^{\Lambda t} V$.

Another group of methods is based on finding a suitable power of two that speeds up the computation.

Matrix Powering

Assuming that we seek $\pi(t)$, let m be an integer and $t_0 \neq 0$ for which $t = 2^m t_0$. Now $t_j = 2t_{j-1}$ for $j \geq 1$, and this implies

$$e^{Qt_j} = P(t_j) = P(t_{j-1})P(t_{j-1}).$$

The idea is to compute $P(t_0)$, then to square it m times to obtain $P(t_m)$, and finally to premultiply $P(t_m)$ with $\pi(0)$.

The uniformization method can be used to compute $P(t_0)$ with a Horner-type scheme when n is small. The recommended value for $m = \log_2(t/t_0)$ due to Marie [4], is

$$m = \lfloor \log_2 [4(\zeta + 3)\Gamma] \rfloor$$

where ζ is the maximum number of nonzero elements in any row of P . The advantage of this method is that the transient solution is also available at intermediate times $t_0, 2t_0, \dots, 2^{m-1}t_0$. Its disadvantages are that the computational cost is proportional to $O(n^3)$ flops, and there is rounding error buildup when $m \gg 1$.

Another way to compute $P(t_0)$ is to use *diagonal Padé approximants* since they are more stable and of higher order than non-diagonal Padé approximants for the same amount of computation. The (p, p) diagonal Padé approximant to e^X , where $X = Qt_0$, is the unique rational function

$$R_{p,p}(X) = \frac{N_{p,p}(X)}{N_{p,p}(-X)}$$

which matches the Taylor series expansion of e^X through terms to the power $2p$. Its coefficients are determined by solving

$$N_{p,p}(X) = \sum_{j=0}^p c_j X^j, \text{ where } c_0 = 1, \\ c_j = c_{j-1} \frac{p+1-j}{j(2p+1-j)}.$$

Efficient Horner-type implementations are possible. Even values of p are better than odd values and $p = 6$ is generally satisfactory [5].

Ordinary Differential Equation Solvers

There are numerous possibilities for applying ODE procedures to compute transient solutions of Markov chains. An immediate advantage of such an approach is that, unlike uniformization and matrix scaling and powering, ODE solution methods are directly applicable to *nonhomogeneous* Markov

chains. Given a first-order differential equation $y' = f(t, y)$ and an initial condition $y(t_0) = y_0$, a solution is a differentiable function $y(t)$ such that

$$y(t_0) = y_0, \frac{d}{dt}y(t) = f(t, y(t)). \quad (5)$$

In the context of Markov chains, the solution $y(t)$ is the row vector $\pi(t)$ and the function $f(t, y(t))$ is simply $\pi(t)Q$.

Numerical procedures to compute the solution of Equation (2) attempt to follow a unique solution curve from its value at an initially specified point to its value at some other prescribed point τ . This usually involves a discretization procedure on the interval $[0, \tau]$ and the computation of approximations to the solution at the intermediate points. Given a discrete set of points (or *mesh*) $\{0 = t_0, t_1, t_2, \dots, t_\eta = \tau\}$ in $[0, \tau]$, we denote the exact solution of the differential Equation (2) at time t_i by $y(t_i)$. The *step size* or *panel width* at step i is defined as $h_i = t_i - t_{i-1}$. A numerical method generates a sequence $\{y_1, y_2, \dots, y_\eta\}$ such that y_i is an approximation to $y(t_i)$. The reader should be careful not to confuse y_i with $y(t_i)$. We use y_i for $i \neq 0$ to denote a *computed approximation* to the *exact value* $y(t_i)$. For $i = 0$, the initial condition gives $y_0 = y(t_0)$.

In computing y_{i+1} , a method may incorporate the values of previously computed approximations y_j for $j = 0, 1, \dots, i$, or even previous approximations to $y(t_{i+1})$. A method that uses only (t_i, y_i) to compute y_{i+1} is said to be an *explicit single-step method*. It is said to be a *multistep method* if it uses approximations at several previous steps to compute its new approximation. A method is said to be *implicit* if computation of y_{i+1} requires an approximation to $y(t_{i+1})$; otherwise, it is said to be *explicit*. We present two elementary methods to illustrate different possibilities.

If the solution is continuous and differentiable, then in a small neighborhood of the point (t, y_i) we can approximate the solution curve by its tangent y'_i at (t_i, y_i) and thereby move from (t_i, y_i) to the next point (t_{i+1}, y_{i+1}) . This method is called the *forward Euler method* (FEM). It is equivalent to a Taylor series expansion of order 1. In the

context of Markov chains, it becomes

$$\pi_{(i+1)} = \pi_{(i)} + h_{i+1}\pi_{(i)}Q. \quad (6)$$

Note that $\pi_{(i)}$ is the *state vector* of probabilities at time t_i . We use this notation, rather than π_i , so as not to confuse the i th component of the vector with the entire vector at time t_i . Thus, moving from one time step to the next is accomplished by a scalar–matrix product and a vector–matrix product.

The *modified Euler method* incorporates the average of the slopes at both points under the assumption that this will provide a better average approximation of the slope over the entire panel $[t_i, t_{i+1}]$. The formula is given by

$$y_{i+1} = y_i + h_{i+1} \frac{f(t_i, y_i) + f(t_{i+1}, y_{i+1})}{2}. \quad (7)$$

This is also referred to as the *trapezoid rule*. When applied to Markov chains, we have

$$\pi_{(i+1)} = \pi_{(i)} + \frac{h_{i+1}}{2} (\pi_{(i)}Q + \pi_{(i+1)}Q),$$

that is,

$$\pi_{(i+1)} \left(I - \frac{h_{i+1}}{2} Q \right) = \pi_{(i)} \left(I + \frac{h_{i+1}}{2} Q \right), \quad (8)$$

which requires in addition to the operations needed by the explicit Euler method, the solution of a system of equations at each step (plus a scalar–matrix product). These additional computations per step are offset to a certain extent by the better accuracy achieved with the trapezoid rule. If the size of the Markov chain is small and the step size is kept constant, the matrix

$$\left(I + \frac{h_{i+1}}{2} Q \right) \left(I - \frac{h_{i+1}}{2} Q \right)^{-1}$$

may be computed at the outset before beginning the stepping process, so that the computation per step required by the modified Euler method becomes identical to that of the explicit Euler. If the Markov chain is large, then the inverse should not be formed explicitly. Instead, an *LU* decomposition should be computed and the inverse replaced with

a backward and forward substitution process with U and L respectively. When the step size is not kept constant, each different value of h used requires that a system of linear equations be solved. Depending on the size and sparsity pattern of Q , the work required by the trapezoid rule to compute the solution to a specified precision may or may not be less than that required by explicit Euler. The trade-off is between an implicit method requiring more computation per step but fewer steps and an explicit method requiring more steps but less work per step! We chose these two simple methods just to illustrate the approach used to compute transient distributions of Markov chains. However, it is more common to use more efficient but more complex methods such as the single-step Runge–Kutta formula and multistep *backward differentiation formulae* (BDF) which we now briefly describe.

Runge–Kutta Methods. A Runge–Kutta algorithm of order p provides an accuracy comparable to a Taylor series algorithm of order p , but without the need to determine and evaluate the derivatives $f', f'', \dots, f^{(p-1)}$, requiring instead the evaluation of $f(t, y)$ at selected points. The derivation of an order p Runge–Kutta method is obtained from a comparison with the terms through h^p in the Taylor series method for the first step, that is, the computation of y_1 from the initial condition (t_0, y_0) . The most widely used Runge–Kutta methods are of order 4. When the standard explicit fourth-order Runge–Kutta method is applied to the Chapman–Kolmogorov equations $\pi' = \pi Q$, the sequence of operations to be performed to move from $\pi_{(i)}$ to the next time step $\pi_{(i+1)}$ is as follows:

$$\pi_{(i+1)} = \pi_{(i)} + h(k_1 + 2k_2 + 2k_3 + k_4)/6,$$

where

$$\begin{aligned} k_1 &= \pi_{(i)} Q, \\ k_2 &= (\pi_{(i)} + hk_1/2) Q, \\ k_3 &= (\pi_{(i)} + hk_2/2) Q, \\ k_4 &= (\pi_{(i)} + hk_3) Q. \end{aligned}$$

Multistep BDF Methods. An important characterization of initial-value ODEs has yet to be discussed: that of *stiffness*. Explicit methods have enormous difficulty solving stiff ODEs, indeed to such an extent that one definition of stiff equations is “problems for which explicit methods don’t work” [6]! Many factors contribute to stiffness, including the eigenvalues of the Jacobian $\partial f/\partial y$ and the length of the interval of integration. The problems stem from the fact that the solutions of stiff systems of differential equations contain rapidly decaying transient terms.

The so-called BDF (*BDF*) methods [7] are a class of multistep methods that are widely used for stiff systems. Only implicit versions are in current use, since low-order explicit versions correspond to the explicit Euler method ($k = 1$) and the midpoint rule ($k = 2$), and higher-order explicit versions ($k \geq 3$) are not stable. Implicit versions are constructed by generating an interpolating polynomial $z(t)$ through the points (t_j, y_j) for $j = i - k + 1, \dots, i + 1$. However, now y_{i+1} is determined so that $z(t)$ satisfies the differential equation at t_{i+1} , that is, in such a way that $z'(t_{i+1}) = f(t_{i+1}, y_{i+1})$. It is usual to express the interpolating polynomial in terms of backward differences

$$\nabla^0 f_i = f_i, \quad \nabla^{j+1} f_i = \nabla^j f_i - \nabla^j f_{i-1}.$$

With this notation, the general formula for implicit BDF methods is

$$\sum_{j=1}^k \frac{1}{j} \nabla^j y_{i+1} = h f_{i+1}$$

and the first three rules are

$$\begin{aligned} k = 1 : y_{i+1} - y_i &= h f_{i+1} \text{ (implicit Euler),} \\ k = 2 : 3y_{i+1}/2 - 2y_i + y_{i-1}/2 &= h f_{i+1}, \\ k = 3 : 11y_{i+1}/6 - 3y_i + 3y_{i-1}/2 - y_{i-2}/3 &= h f_{i+1}. \end{aligned}$$

The BDF formulae are known to be stable for $k \leq 6$ and to be unstable for other values of k . When applied to Markov chains, the implicit ($k = 2$) BDF formula is

$$3\pi_{(i+1)}/2 - 2\pi_{(i)} + \pi_{(i-1)}/2 = h\pi_{(i+1)} Q,$$

so that the system of equations to be solved at each step is

$$\pi_{(i+1)}(3I/2 - hQ) = 2\pi_{(i)} - \pi_{(i-1)}/2. \quad (9)$$

The solutions at two prior points $\pi_{(i-1)}$ and $\pi_{(i)}$ are used in the computation of $\pi_{(i+1)}$. To get the procedure started, the initial starting point $\pi_{(0)}$ is used to generate $\pi_{(1)}$ using the trapezoid rule, and then both $\pi_{(0)}$ and $\pi_{(1)}$ are used to generate $\pi_{(2)}$, using Equation (9).

EXAMPLE

Let us consider the CTMC whose transition-rate matrix is given by

$$Q = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix},$$

and investigate the outcome of applying the methods of matrix decomposition and explicit Runge–Kutta of order 4 with the initial probability vector $\pi(0) = (10)$ for time $t = 1$.

The generator matrix has the decomposition $Q = S^{-1}\Lambda S$, where

$$S = \begin{pmatrix} \sqrt{2}/2 & \sqrt{2}/2 \\ -\sqrt{2}/2 & \sqrt{2}/2 \end{pmatrix} \quad \text{and} \quad \Lambda = \begin{pmatrix} 0 & 0 \\ 0 & -2 \end{pmatrix}.$$

Since $\pi(t) = \pi(0)S^{-1}e^{\Lambda t}S$, we have $\pi(1) = (0.5677, 0.4323)$ in four decimal digits of precision.

As for the Runge–Kutta method of order 4 with the step size $h = 0.25$, for four steps we obtain in four decimal digits of precision $\pi_1 = (0.8034, 0.1966)$, $\pi_2 = (0.6481, 0.3519)$, $\pi_3 = (0.6117, 0.3883)$, and $\pi_4 = (0.5678, 0.4322)$.

COMPUTATIONAL METHODS FOR DTMCs

Carolina State University, Raleigh,
North Carolina

A *discrete-time Markov chain* (DTMC) $\{X_n, n = 0, 1, 2, \dots\}$ is a stochastic process, such that for all natural numbers n and all states $i, j, k, l, \dots$,

$$\text{Prob}\{X_{n+1} = j | X_n = i, X_{n-1} = k, \dots, X_0 = l\} \\ = \text{Prob}\{X_{n+1} = j | X_n = i\}.$$

Thus the state in which the system finds itself at time step $n + 1$ depends only on where it is at time step n . The conditional probabilities, $\text{Prob}\{X_{n+1} = j | X_n = i\}$, are called the *single-step transition probabilities*, or just the transition probabilities, of the DTMC. They give the conditional probability of making a transition from state i to state j when the time parameter increases from n to $n + 1$. They are denoted by

$$p_{ij}(n) = \text{Prob}\{X_{n+1} = j | X_n = i\}.$$

The matrix $P(n)$, formed by placing $p_{i,j}(n)$ in row i and column j , for all i and j , is called the *transition probability matrix*. It follows that a DTMC is completely characterized by its transition probability matrix $P(n)$ and a probability vector $\pi(0)$ whose i th element gives the probability of the chain beginning at time step 0 in state i . The DTMC is said to be (*time*) *homogeneous* if for all states i and j ,

$$\text{Prob}\{X_{n+1} = j | X_n = i\} = \text{Prob}\{X_{n+m+1} = j | \\ X_{n+m} = i\},$$

for $n = 0, 1, 2, \dots$ and $m \geq 0$. For a homogeneous DTMC,

$$p_{ij} = \text{Prob}\{X_1 = j | X_0 = i\} = \text{Prob}\{X_2 = j | \\ X_1 = i\} = \text{Prob}\{X_3 = j | X_2 = i\} = \dots$$

and we can replace $P(n)$ with P , since transitions no longer depend on n . In this article, we consider only homogeneous DTMCs.

After n steps, the probability distribution of a DTMC with transition probability matrix P and initial probability distribution $\pi(0)$ is given by

$$\pi(n) = \pi(n-1)P = \pi(n-2)P^2 = \dots = \pi(0)P^n.$$

These distributions are generally referred to as *transient* distributions and their computation rarely poses major problems. The procedure consists of repeatedly multiplying the probability distribution vector obtained at step $(k-1)$ with the stochastic transition probability matrix to obtain the probability distribution at step k , for $k = 1, 2, \dots, n$. If n is large and the number of states in the DTMC is small (not exceeding several hundreds), then some savings in computation time can be obtained by successively squaring the transition probability matrix j times, where j is the largest integer such that $2^j \leq n$. This gives the matrix P^{2^j} which can now be multiplied by P (and powers of P) until the value P^n is obtained. The distribution at time step n is now found from $\pi(n) = \pi(0)P^n$. If the matrix P is sparse, this sparsity is lost in the computation of P^n , so this approach is not appropriate for large sparse DTMCs. Also, if a time trajectory of a statistic of the distribution is needed, this approach may be less than satisfactory, because only distributions at computed values of P^{2^j} will be available. One final point worth noting is that for large values of n , it may be beneficial to maintain a check on successive distributions since they may converge to some desired computational accuracy, prior to step n . Any additional vector-matrix multiplications after this point will not alter the distribution.

If $\lim_{n \rightarrow \infty} P^n$ exists, then $\lim_{n \rightarrow \infty} \pi(n) = \pi(0) \lim_{n \rightarrow \infty} P^n$ exists and is called the

limiting distribution. Not all DTMCs possess a limiting distribution: a periodic DTMC (upon exiting any state, a return to that state can occur only in some multiple of $c > 1$ steps) does not possess a limiting distribution. A limiting distribution which converges, independent of the initial starting distribution $\pi(0)$, to a vector whose components are strictly positive and sum to 1, is called a *steady-state* distribution. Thus, a steady-state distribution is the unique vector π that satisfies

$$\begin{aligned}\pi &= \pi(0) \lim_{n \rightarrow \infty} P^{(n)} = \pi(0) \lim_{n \rightarrow \infty} P^{(n+1)} \\ &= \left[\pi(0) \lim_{n \rightarrow \infty} P^{(n)} \right] P = \pi P,\end{aligned}$$

that is, $\pi = \pi P$. Any probability vector z (the components are probabilities and sum to 1) such that $z = zP$ is called a *stationary* distribution. Some DTMCs may contain multiple stationary distributions while others may have none. When a steady-state distribution π exists, it is the unique stationary distribution. Unless explicitly stated otherwise, in this article we consider *ergodic* DTMCs which have a (unique) steady-state distribution and, for the most part, our objective is to compute this distribution from the defining relationship, $\pi = \pi P$.

We distinguish between solution methods that are *iterative* and solution methods that are *direct*. Iterative methods begin with an initial approximation (or guess) to the solution vector and proceed to modify this approximation in such a way that, at each step of iteration, it becomes closer and closer to the true solution. On the other hand, a direct method attempts to go straight to the final solution. A certain number of well defined steps must be taken, at the end of which the solution has been computed.

Iterative methods of one type or another are by far the most commonly used methods for solving DTMCs. There are several important reasons for this choice. First, an examination of the standard iterative methods shows that the only operation in which the matrices are involved is their multiplication with one or more vectors or with preconditioners—operation which leaves the transition matrices unaltered. Thus, compact

storage schemes, which minimize the amount of memory required to store the matrix and which, in addition, are well suited to matrix multiplication, may be conveniently implemented. Since the matrices involved are usually large and very sparse, the savings made by such schemes can be considerable. With direct equation-solving methods, the elimination of one nonzero element of the matrix during the reduction phase often results in the creation of several nonzero elements in positions which previously contained zeroes. This is called *fill-in*, and not only does it make the organization of a compact storage scheme more difficult, since provision must be made for the deletion and the insertion of elements, but, in addition, the amount of fill-in can often be so extensive that available memory can be exhausted.

Iterative methods have other advantages. Use may be made of good initial approximations to the solution vector, and this is especially beneficial when a series of related experiments are being conducted. Also, an iterative process may be halted once a pre-specified tolerance criterion has been satisfied, and this may be relatively lax. In contrast, a direct method must continue until the final specified operation has been carried out. And lastly, with iterative methods, the matrix is never altered and hence the build-up of rounding error is, to all intents and purposes, nonexistent. For these reasons, iterative methods have traditionally been preferred to direct methods. However, iterative methods have a major disadvantage in that often they require a very long time to converge to the desired solution. Direct methods have the advantage that an upper bound on the time required to obtain the solution may be determined before the computation is initiated. More important, for certain classes of problems, direct methods can result in a much more accurate answer being obtained in less time. Since iterative methods will in general require less memory than direct methods, these latter can only be recommended if they obtain the solution in less time.

The most suitable candidates for solution by direct methods are DTMCs whose transition matrices are small, of the order of a few

hundred, or when they are *banded*, that is, the only nonzero elements of the coefficient matrix are not too far from the diagonal. In this latter case, it means that an ordering can be imposed on the states so that no single-step transition from state i will take it to states numbered greater than $i + \delta$ or less than $i - \delta$. All fill-in will occur within a distance δ of the diagonal, and the amount of computation per step is proportional to δ^2 . We begin with direct methods based on Gaussian elimination.

DIRECT METHODS FOR SOLVING DTMCs

Gaussian elimination (GE) is a direct method for solving systems of linear equations which are usually written in the form $Ax = b$, where A is an $(n \times n)$ coefficient matrix, x the unknown column vector of length n which is to be found, and b the right-hand side column vector of length n . In our case, we seek to determine π from the system of equations $\pi = \pi P$, that is, from

$$\pi(P - I) = 0, \quad (1)$$

where I is the identity matrix. In the standard equation-solving terminology, $A = P^T - I$, $x = \pi^T$, and $b = 0$. The system of equations (Eq. 1) has a solution other than the trivial solution ($\pi_i = 0$, for all i) if and only if the coefficient matrix is singular. Since the determinant of a matrix is equal to the product of its eigenvalues and since P possesses an eigenvalue equal to 1, the singularity of A and hence the existence of a nontrivial solution follows. In passing, we remark that in the DTMC context, A is a negated *M-matrix*.

GE is composed of two phases, a *reduction* phase during which the coefficient matrix is brought to upper triangular form, and a *backsubstitution* phase which generates the solution from the reduced coefficient matrix. The first (reduction) phase is the computationally expensive part of the algorithm, having an $O(n^3)$ operation count when the matrix is full. The backsubstitution phase has order $O(n^2)$. The first step in GE is to use one of the equations to eliminate one of the unknowns in the other $(n - 1)$ equations.

This is accomplished by adding a multiple of one row to the other rows; the particular multiple is chosen to zero out the coefficient of the unknown to be eliminated. The particular equation chosen is called the *pivotal equation* and the diagonal element in this equation is called the *pivot*. The equations that are modified are said to be *reduced*. The operations of multiplying one row by a scalar and adding or subtracting two rows are *elementary operations*; they leave the system of equations invariant. When the first step of GE is finished, one equation involves all n unknowns while the other $(n - 1)$ equations involve only $(n - 1)$ unknowns. These $(n - 1)$ equations may be treated independent of the first. They constitute a system of $(n - 1)$ linear equations in $(n - 1)$ unknowns, which we may now solve using GE and thus the process continues. Initially, $1 - p_{i,i} = \sum_{j \neq i} p_{i,j}$ and this property is maintained during the reduction phase. Therefore, at each step of the reduction, the pivotal elements are the largest in each column, and the multipliers do not exceed 1. Explicit pivoting, which is used in general systems of linear equations to ensure that multipliers do not exceed 1, is generally not needed for solving DTMC problems.

At the end of the reduction phase, we would hope to end up with one equation in one unknown, two equations in two unknowns, and so on, up to n equations in n unknowns. However, A has rank $(n - 1)$, since we assume that the DTMC is ergodic, and the last equation in the reduced system must evaluate to $0 = 0$. Another way to look at this situation is to observe that the system of equations $Ax = 0$ does not tell the whole story. We also know that $e^T x = 1$, where e is a column vector containing n 1's. The n equations of $Ax = 0$ provide only $(n - 1)$ linearly independent equations, but together with $e^T x = 1$, we have a complete basis set. For example, it is possible to replace the last equation of the original system with $e^T x = 1$, which eliminates the need for any further normalization. In this case the coefficient matrix becomes nonsingular, the right-hand side becomes nonzero, and a unique solution is computed. Of course, it is not necessary to replace the last equation of the system by this normalization equation. Indeed, any

equation could be replaced. However, this is generally undesirable, for it will entail more numerical computation. For example, if the first equation is replaced, the first row of the coefficient matrix will contain all 1's and the right-hand side will be $e_1 = (1, 0, \dots, 0)^T$. The first consequence of this is that during the reduction phase, the entire sequence of elementary row operations must be performed on the right-hand side vector, e_1 , whereas if the last equation is replaced, the right-hand side is unaffected by the elementary row operations. The second and more damaging consequence is that substantial fill-in will occur since a multiple of the first row, which contains all 1's, will be added to higher numbered rows and a cascading effect will undoubtedly occur in all subsequent reduction steps. An equally viable alternative to replacing the last equation with $e^T x = 1$ is to set the last component x_n to 1 and leave a final normalization until later.

Once the reduction phase of GE is finished, we proceed to the backsubstitution phase, during which the values of the unknowns are computed. Given one equation in one unknown (the last equation in the reduced system), the value of that unknown is easily computed. Since we now know x_n , the value of x_{n-1} can be found from the penultimate equation in the reduced system. The process of back substitution continues in this manner until all the unknowns have been evaluated.

Connection to LU Factorization

When the coefficient matrix in a system of linear equations $Ax = b$ can be written as the product of a lower triangular matrix L and an upper triangular matrix U , then

$$Ax = LUx = b$$

and the solution can be found by first solving (by forward substitution) $Lz = b$ for an intermediate vector z and then solving (by back substitution) $Ux = z$ for the solution x . The upper triangular matrix obtained by the reduction phase of GE provides an upper triangular matrix U to go along with a lower triangular matrix L whose diagonal elements are all equal to 1 and whose subdiagonal

elements are the multipliers with a minus sign in front of them.

In the DTMC context, the system of equations is homogeneous and the coefficient matrix is singular,

$$(P^T - I)x = (LU)x = 0.$$

If we now set $Ux = z$ and attempt to solve $Lz = 0$, we find that, since L is nonsingular (it is a triangular matrix whose diagonal elements are all equal to 1), we must have $z = 0$. This means that we may proceed directly to the back substitution on $Ux = z = 0$ with $u_{nn} = 0$. It is evident that we may assign any nonzero value to x_n , say $x_n = \eta$, and then determine, by simple back substitution, the remaining elements of the vector x in terms of η . Normalizing the solution obtained from solving $Ux = 0$ yields the desired unique solution vector π . This approach is referred to as an *LU decomposition* or *LU factorization*.

Grassmann–Taksar–Heyman Idea

It is appropriate at this point to mention a version of GE that has attributes that appear to make it even more stable than the usual version. This procedure is commonly referred to as the *Grassmann–Taksar–Heyman* (GTH) algorithm [1,2]. In the GTH idea, the diagonal elements are obtained by summing off-diagonal elements rather than performing subtractions: it is known that subtractions can sometimes lead to loss of significance in numerical computations. These subtractions occur in forming the diagonal elements during the reduction process. Happily, it turns out that at the end of each reduction step, the unreduced portion of the matrix is the transpose of a submatrix with nonnegative off-diagonal elements and the diagonal elements can be formed as the negated sums of these off-diagonal elements. This has a probabilistic interpretation based on the restriction of the DTMC to a reduced set of states and it is in this context that the GTH algorithm is generally developed. It also means that the diagonal elements may be formed by adding off-diagonal elements and placing a minus sign in front of this sum instead of performing a single subtraction.

Moments of First Passage Times

Before terminating this section on direct methods for finding steady-state distributions, we consider the problem of computing moments of first passage times from a state to a set of states in DTMCs. Without loss of generality, let us assume that the state space of P is partitioned as $\mathcal{S} = \mathcal{F} \cup \mathcal{T}$, $\mathcal{F} \cap \mathcal{T} = \emptyset$, yielding the block partitioning

$$P = \begin{pmatrix} P_{\mathcal{F},\mathcal{F}} & P_{\mathcal{F},\mathcal{T}} \\ P_{\mathcal{T},\mathcal{F}} & P_{\mathcal{T},\mathcal{T}} \end{pmatrix}$$

Now, let $\mathcal{F}$ have $n_{\mathcal{F}}$ states and $\mathcal{T}$ have $n_{\mathcal{T}}$ states so that $n = n_{\mathcal{F}} + n_{\mathcal{T}}$.

In Ref. 3, an algorithm is given to compute *moments of first passage times* from states in $\mathcal{F}$ to $\mathcal{T}$ using the recurrence

$$Fm^{(i+1)} = \sum_{j=0}^i (-1)^{i-j} \binom{i+1}{j} m^{(j)} \quad \text{for } i \geq 0 \text{ with } m^{(0)} = e, \quad (2)$$

where $F = I - P_{\mathcal{F},\mathcal{F}}$, $m_f^{(j)}$ is the j th moment of first passage time from state $f \in \mathcal{F}$ to $\mathcal{T}$, and $\binom{i+1}{j}$ denotes the *binomial coefficient* $(i+1) \text{ choose } j$. The integer coefficients of the linear combination on the right-hand side of Equation (2) may easily be computed by observing the alternating signs and using the identity $\binom{i+1}{j} = \binom{i}{j-1} + \binom{i}{j}$.

In order to carry out the moment computation accurately, a nonhomogeneous but consistent linear system $Ax = b$, where

$$B = \begin{pmatrix} I - P_{\mathcal{F},\mathcal{F}} & -P_{\mathcal{F},\mathcal{T}}e \\ w^T & -w^T e \end{pmatrix}, \quad x = \begin{pmatrix} y \\ 0 \end{pmatrix}, \quad \text{and} \quad b = \begin{pmatrix} c \\ v \end{pmatrix},$$

is considered. Observe that B is a singular M-matrix with zero row sums and has rank $n_{\mathcal{F}}$. Hence, $F = I - P_{\mathcal{F},\mathcal{F}}$ can be LU factored in $(n_{\mathcal{F}} - 1)$ reduction steps using the GTH idea, thus making the values of the vector w and the scalar v immaterial. Then y can be obtained from $LUy = c$ through forward and back substitutions. Note that both L and U need to be stored since Equation (2) will be solved for multiple right-hand sides.

The reason behind using the GTH idea is to improve the accuracy in the computed factors when F is close to being singular. Other than providing better roundoff properties, this modification has the additional advantage of being carried out completely in row-wise sparse format with delayed row updates. Otherwise, one could employ GE to factorize F , but in no way should it be inverted and passed to the right-hand side in Equation (2).

ITERATIVE METHODS FOR SOLVING DTMCs

Up until this section, direct methods which execute for a predetermined number of steps are discussed. For large problems, direct methods become inefficient, because they introduce new nonzero elements during factorization. The class of methods introduced here are iterative in that they begin from some initial approximation and compute a new approximation at each iteration while maintaining the nonzero structure of the coefficient matrix, with the expectation that the approximation converges to the steady-state vector. Since the number of iterations required to reach a predetermined accuracy cannot be forecast inexpensively other than in some special cases, rules of thumb regarding the performance of iterative methods were investigated in a sequence of papers [4–7].

There are different classes of iterative methods. The taxonomy considered here consists of those methods that are based on splitting the coefficient matrix, decomposing the coefficient matrix, and using Krylov subspaces. At each iteration, each of these class of methods performs some number of matrix-vector multiplications and in certain cases the direct/iterative solution of linear systems, which are sometimes smaller than the original system of equations.

Methods Based on Splittings

Methods based on splittings are stationary iterative methods in which the singular coefficient matrix $A = P^T - I$ of the homogeneous linear system $Ax = 0$ to be solved for $x = \pi^T$ is written as the difference of two matrices,

the first being nonsingular. They include the *power* (POWER) method, *(block) Jacobi over-relaxation* ((B)JOR), and *(block) successive overrelaxation* ((B)SOR). We remark that the POWER method has been used extensively to compute the eigenvector corresponding to the dominant eigenvalue of a matrix, and can also be viewed as a relaxation of the Richardson type.

Let us consider the block partitioning of A and x given, respectively, by

$$A = \begin{pmatrix} A_{1,1} & A_{1,2} & \cdots & A_{1,K} \\ A_{2,1} & A_{2,2} & \cdots & A_{2,K} \\ \vdots & \vdots & \ddots & \vdots \\ A_{K,1} & A_{K,2} & \cdots & A_{K,K} \end{pmatrix}, \quad x = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_K \end{pmatrix}$$

for some number of blocks $K \in \{1, 2, \dots, n\}$, and write A as the sum of three terms as in

$$A = D_A - L_A - U_A,$$

where D_A is the block diagonal of A , $-L_A$ is its strictly block lower triangular part, and $-U_A$ is its strictly block upper triangular part. In other words,

$$D_A = \begin{pmatrix} A_{1,1} & 0 & \cdots & 0 \\ 0 & A_{2,2} & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & A_{K,K} \end{pmatrix},$$

$$L_A = - \begin{pmatrix} 0 & 0 & \cdots & 0 \\ A_{2,1} & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ A_{K,1} & \cdots & A_{K,K-1} & 0 \end{pmatrix},$$

$$U_A = - \begin{pmatrix} 0 & A_{1,2} & \cdots & A_{1,K} \\ 0 & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & A_{K-1,K} \\ 0 & 0 & \cdots & 0 \end{pmatrix}.$$

If A is irreducible, each of the terms D_A , U_A , and L_A is nonpositive, and $a_{s,s} < 0$ for all $s \in \mathcal{S}$, implying the existence of D_A^{-1} and $(D_A - L_A)^{-1}$.

Now, let A be split as

$$A = M_A - N_A,$$

and let us define the iteration matrices

$$T_A = M_A^{-1}N_A$$

of the POWER, (B)JOR, and (B)SOR methods to compute the sequence of approximations

$$x^{(m+1)} = T_A x^{(m)} \quad \text{for } m = 0, 1, \dots$$

The particular splittings corresponding to the three methods are

$$\begin{aligned} M_A^{\text{POWER}} &= -I, \quad N_A^{\text{POWER}} = -(I + A), \\ M_A^{(\text{B})\text{JOR}} &= D_A/\omega, \quad N_A^{(\text{B})\text{JOR}} \\ &= (1 - \omega)D_A/\omega + L_A + U_A, \\ M_A^{(\text{B})\text{SOR}} &= D_A/\omega - L_A, \quad N_A^{(\text{B})\text{SOR}} \\ &= (1 - \omega)D_A/\omega + U_A, \end{aligned}$$

where $\omega \in (0, 2)$ is the relaxation parameter of (B)JOR and (B)SOR. The BJOR and BSOR splittings reduce to block Jacobi (BJ) and block Gauss–Seidel (BGS) splittings for $\omega = 1$, and to point JOR and point SOR for $K = n$ (i.e., when the number of blocks is equal to the number of unknowns). Hence, the iteration matrices corresponding to the three splittings are

$$\begin{aligned} T_A^{\text{POWER}} &= I + A, \\ T_A^{(\text{B})\text{JOR}} &= (1 - \omega)I + \omega D_A^{-1}(L_A + U_A) \quad \text{and} \\ T_A^{(\text{B})\text{SOR}} &= (D_A/\omega - L_A)^{-1}((1 - \omega)D_A/\omega + U_A). \end{aligned}$$

Observe that the relation $T_A x = x$ holds (i.e., x is a fixed point of T_A) for the POWER, (B)JOR, and (B)SOR methods.

If $\omega \in (0, 1)$, then the iteration matrix T_A is nonnegative, irreducible, primitive, and has a spectral radius and an eigenvalue of 1; hence, convergence is guaranteed. For a sequence of converging approximations, one needs to ensure for the initial approximation that $x^{(0)} \notin \text{Range}(I - T_A)$; otherwise, there will be no improvement.

It is well known that the asymptotic rate of convergence of the methods under consideration depends on the magnitude of the subdominant eigenvalue of T_A . The smaller its value, the faster the method

converges. Regarding nonasymptotic convergence behavior, it can be said that there will be improvement in the current approximate solution vector $x^{(m)}$ compared to the initial approximate solution vector $x^{(0)}$ if T_A^m is positive or has a (an almost) positive row or column [8, p. 1041]. The coefficient matrix A is almost always sparse and the iteration matrices associated with the POWER and JOR methods have the same off-diagonal nonzero structure as that of A . Hence, compared to POWER and JOR, SOR has a higher chance of satisfying the conditions for improvement, since its iteration matrix is likely to have a larger number of nonzeros. In general, block iterative methods require more computation per iteration than point iterative methods based on splittings, but this is offset by a faster rate of convergence.

Regarding implementation, it is useful to consider the formulation of the POWER method in

$$x^{(m+1)} = P^T x^{(m)} \quad \text{for } m = 0, 1, \dots,$$

whereas those of (B)JOR and (B)SOR methods, respectively, in

$$\begin{aligned} A_{k,k}x_k^{(m+1)} &= (1 - \omega)A_{k,k}x_k^{(m)} \\ &\quad - \omega \left(\sum_{j=1}^{k-1} A_{k,j}x_j^{(m)} + \sum_{j=k+1}^K A_{k,j}x_j^{(m)} \right) \\ &\quad \text{for } k = 1, 2, \dots, K \end{aligned}$$

and

$$\begin{aligned} A_{k,k}x_k^{(m+1)} &= (1 - \omega)A_{k,k}x_k^{(m)} \\ &\quad - \omega \left(\sum_{j=1}^{k-1} A_{k,j}x_j^{(m+1)} + \sum_{j=k+1}^K A_{k,j}x_j^{(m)} \right) \\ &\quad \text{for } k = 1, 2, \dots, K \end{aligned}$$

for $m = 0, 1, \dots$. Note that the POWER method amounts to a matrix-vector multiplication, whereas (B)JOR and (B)SOR amount to (sub)matrix-(sub)vector multiplications, some vector operations, and, when $K \neq n$, solutions of nonhomogenous linear systems with nonsingular coefficient matrices $A_{k,k}$ for $k = 1, 2, \dots, K$.

When information about a suitable starting point is not known, the initial approximation is chosen as the uniform distribution. The solution vector may be normalized every few iterations to limit the effect of underflow and overflow, and to a certain extent control any irregular convergence behavior. The convergence criteria to be used in these iterative solvers could be, for instance,

$$\text{stop if } m \geq \text{maxit} \text{ or } \|r^{(m)}\|_\infty \leq \text{stop_tol}.$$

Here m is the iteration number, $r^{(m)}$ is the residual vector at iteration m , maxit is the maximum number of iterations the method is permitted to perform, and stop_tol is the user-specified stopping tolerance, which should be less than 1 and greater than machine epsilon. Setting stop_tol to a particular value means that the entries of A (our right-hand side is 0) are considered to have errors in the range $\pm \text{stop_tol} \|A\|$. Note that the computation of $r^{(m)}$ requires a matrix-vector multiplication and should not be performed at each iteration; otherwise, the work done per iteration would double.

In passing to iterative methods based on decomposing the coefficient matrix, we remark that in this section we considered *forward* versions of iterative methods based on splittings. In other words, in a given iteration the first unknown to be updated corresponded to the first state of the underlying DTMC, the next unknown to the second state, and so on. However, it is also possible to update the unknowns in reverse order, starting from the last one and moving toward the first state. This approach is referred to as *backward*. Although it would not make any difference on the magnitude of the subdominant eigenvalue of T_A for POWER and (B)JOR methods, the magnitude of the subdominant eigenvalue of T_A for (B)SOR changes when the states of the underlying DTMC are *renumbered*. This situation gives rise to the idea of using forward and backward versions of (B)SOR simultaneously, and thus to the concept of *symmetric* B(SOR). The effect of renumbering the states of a DTMC (i.e., *symmetrically permuting* A) on convergence is briefly investigated for the GS iteration in Ref. 9 with the result that the

states of the underlying DTMC can always be renumbered so as to ensure convergence.

Decompositional Methods

In the class of decompositional iterative methods for DTMCs, we primarily consider *iterative aggregation-disaggregation* (IAD), which is based on partitioning the state space $\mathcal{S}$ of the DTMC into mutually exclusive subsets $\mathcal{S}_k$ for $k = 1, 2, \dots, K$ (i.e., $\cup_{k=1}^K \mathcal{S}_k = \mathcal{S}$ and $\mathcal{S}_k \cap \mathcal{S}_l = \emptyset$ for $k \neq l$). Thus, P can be symmetrically permuted and partitioned into $(K \times K)$ blocks as in

$$P = \begin{pmatrix} P_{1,1} & P_{1,2} & \cdots & P_{1,K} \\ P_{2,1} & P_{2,2} & \cdots & P_{2,K} \\ \vdots & \vdots & \ddots & \vdots \\ P_{K,1} & P_{K,2} & \cdots & P_{K,K} \end{pmatrix}$$

at the outset of IAD. At each iteration, an aggregated matrix is computed and solved, and this step is preceded and/or succeeded by some number of iterations using a method based on splittings. IAD methods are intimately related to *multigrid* methods [10] and are especially useful when dealing with ill-conditioned systems. There are also *Schwarz* methods, which can be considered as a generalization of block iterative methods based on splittings in which the partitioning of the state space $\mathcal{S}$ into K subsets has overlaps (i.e., $\cup_{k=1}^K \mathcal{S}_k = \mathcal{S}$ and $\mathcal{S}_k \cap \mathcal{S}_l \neq \emptyset$ for $k \neq l$). Their additive versions [11] become BJOR and their multiplicative versions become BSOR when the overlaps are removed. These tend to accelerate the convergence of the corresponding block iterative methods, the amount of acceleration depending on the amount of overlap [12].

Iterative Aggregation-Disaggregation. IAD methods, such as the Koury-McAllister-Stewart (KMS) method [13], are suitable for DTMCs that can be symmetrically permuted to the block form

$$P = \text{diag}(P_{1,1}, P_{2,2}, \dots, P_{K,K}) + E,$$

when $\|E\|_\infty$, the *degree of coupling*, is relatively small compared to 1. In other words, for the specified partitioning, there are strong

interactions among the states of the disjoint subsets but weak interactions among the subsets themselves. Such DTMCs are called *nearly completely decomposable* (NCD) and are known to be ill conditioned due to the existence of $(K - 1)$ eigenvalues close to 1. The smaller the degree of coupling, the closer these other eigenvalues to 1, and the more difficult it is to solve the problem with iterative methods based on splittings.

Once again, letting $A = P^T - I$ and partitioning $x = \pi^T$ conformally with P , the transpose of the $(K \times K)$ matrix H whose (i, j) th element is given by

$$h_{i,j} = e^T A_{i,j} \phi_j,$$

where

$$\phi_j = x_j / \|x_j\|_1$$

is referred to as the *exactly aggregated matrix* corresponding to A . Note that one needs to know the exact solution to be able to compute the exactly aggregated matrix, which suggests approximate aggregation, hence iteration.

Now, let $\xi = (\xi_1, \xi_2, \dots, \xi_K)^T$ be the unique positive vector satisfying $H\xi = 0$, $\sum_{i=1}^K \xi_i = 1$. Then the IAD method with a BGS *disaggregation* step (IADBGS) [5] is equivalent to the iterative formula

$$x^{(m+1)} = (D_A - L_A)^{-1} U_A \Sigma^{(m)} x^{(m)} \quad \text{for } m = 0, 1, \dots,$$

where

$$\begin{aligned} h_{i,j}^{(m)} &= e^T A_{i,j} \phi_j^{(m)}, \quad \phi_j^{(m)} = x_j^{(m)} / \|x_j^{(m)}\|_1, \\ H^{(m)} \xi^{(m)} &= 0, \quad \xi^{(m)} > 0, \quad \sum_{i=1}^K \xi_i^{(m)} = 1, \\ \Sigma^{(m)} &= \text{diag} \left(\xi_1^{(m)} I / \|x_1^{(m)}\|, \xi_2^{(m)} I / \|x_2^{(m)}\|, \right. \\ &\quad \left. \dots, \xi_K^{(m)} I / \|x_K^{(m)}\| \right). \end{aligned}$$

Writing this in detail, one obtains

$$\begin{aligned} A_{i,i} x_i^{(m+1)} &= - \sum_{j=1}^{i-1} A_{i,j} x_j^{(m+1)} - \sum_{j=i+1}^K A_{i,j} x_j^{(m+1)} \\ &\quad \text{for } i = 1, 2, \dots, K, \end{aligned}$$

where

$$z^{(m+1)} = \begin{pmatrix} \xi_1^{(m)} \left(\phi_1^{(m)} \right)^T, \xi_2^{(m)} \left(\phi_2^{(m)} \right)^T, \\ \dots, \xi_K^{(m)} \left(\phi_K^{(m)} \right)^T \end{pmatrix}^T.$$

A similar formula may be written for BJ, and hence, for BJOR and BSOR disaggregation steps.

For NCD MCs the convergence of the IADBGs method will be rapid. Its asymptotic convergence analysis reveals that the error in the approximate solution is reduced by a factor of order $\|E\|_\infty$ at each iteration if the aggregated matrix and each diagonal block are solved exactly [14], for instance, with GE. When GE suffers from instability on aggregated matrices in the presence of rounding errors, one can use GTH [15]. The study of local and global convergence of IAD for arbitrary block partitionings (with the possibility of using iterative solution methods for the aggregation step) appears in Refs 16–18.

Krylov Subspace Projection Methods

Krylov subspace projection methods are non stationary iterative methods in which approximate solutions satisfying various constraints are extracted from small dimensional subspaces. The methods differ among each other in the way subspaces are selected and solution approximations extracted from them [4]. Being iterative, their basic operation is matrix-vector multiplication. Compared to other classes of iterative methods, they require a larger number of work vectors of size equal to the size of the state space, n . But, more importantly, they need to be used with preconditioners to result in effective solvers. The main idea behind preconditioning is to transform the linear system so that the difference between the dominant and the subdominant eigenvalues of the preconditioned coefficient matrix is larger than what it used to be in the original system [19].

A *projection step* is formally defined with a subspace $\mathcal{K}$ of dimension m from which the approximation is to be selected and another subspace $\mathcal{L}$ (of the same size m) that is used to set the constraints necessary to extract

the new approximate solution vector from $\mathcal{K}$. For practical purposes, one should have $m \ll n$. Now, let $V = [v_1, v_2, \dots, v_m]$ and $W = [\omega_1, \omega_2, \dots, \omega_m]$, respectively, be the bases of $\mathcal{K}$ and $\mathcal{L}$. Then taking the linear system $Ax = 0$ view into consideration, it is possible to express the approximate solution as $\tilde{x} = Vy$, where y is a vector of length m . This provides m degrees of freedom, and in order to extract a unique y the residual vector $-A\tilde{x}$ is required to be orthogonal to $\mathcal{L}$; that is,

$$-AVy \perp \omega_i, \quad i = 1, 2, \dots, m,$$

in matrix form,

$$-W^T AVy = 0.$$

If $x^{(0)}$ is an initial approximate solution to the system, then $x^{(0)}$ may be adjusted by a vector δ such that $(x^{(0)} + \delta)$ is a solution, that is, $A(x^{(0)} + \delta) = 0$. If we let $r_0 = -Ax^{(0)}$, then

$$\begin{aligned} A(x^{(0)} + \delta) = 0 &\Rightarrow Ax^{(0)} + A\delta = 0 \\ &\Rightarrow A\delta = -Ax^{(0)} = r_0; \end{aligned}$$

and hence, the projection step is applied to the system $A\delta = r_0$ to compute the unknown vector δ .

Projection methods are classified into two main groups. The first is when the *Krylov subspace* $\mathcal{K}$ is taken as $\mathcal{K} = \mathcal{L} = \text{span}\{r_0, Ar_0, \dots, A^{m-1}r_0\}$ and $V = W$ is an orthogonal basis of $\mathcal{K}$. This represents the class of *orthogonal projection methods* (also known as *Galerkin projection methods*). In this group of methods, each iteration aims to minimize the A-norm of the error vector $(x - \tilde{x})$ in the subspace $\mathcal{K}$. The second group of projection methods is when $\mathcal{L} = A\mathcal{K} = \text{span}\{Ar_0, A^2r_0, \dots, A^mr_0\}$ (and hence $W = AV$). Each iteration of this kind of methods aims to minimize the 2-norm of the residual vector. This explains why the latter class of methods are referred to as *minimal residual methods*.

Popular Methods. The most commonly used Krylov subspace methods are *generalized minimum residual* (GMRES), *biconjugate gradient* (BCG), *conjugate gradient squared* (CGS), *biconjugate gradient*

stabilized (BCGStab), and *quasi-minimal residual* (QMR). Of these, GMRES is a minimal residual method based on the Arnoldi procedure for orthogonalizing the Krylov subspace and storing its basis in a Hessenberg matrix. It is normally used with restarts to control storage requirements by forming the new approximation only after each restart. A nice by-product of GMRES is that the residual norm is available at each iteration without having to compute the approximate solution. BCG is an orthogonal projection method, and it takes an advantage over GMRES by reducing the storage demand. This is achieved by replacing the orthogonal sequence of residuals (formed by GMRES to build the basis of the Krylov subspace) by two mutually orthogonal sequences of residual vectors. However, the convergence behavior of BCG is quite irregular and it also requires a matrix-vector multiplication with the transpose of A . To increase the effectiveness of BCG, variants such as CGS and BCGStab are proposed. The rate of convergence of CGS is generally twice that of BCG. However, this is not always the case since a reduced residual vector may not be reduced any further. This explains the highly irregular convergence behavior of CGS. Moreover, rounding errors are very likely to occur in CGS as corrections to the approximate solution may be very large, and hence the finally computed solution may not be very accurate. CGS is almost as timewise expensive as BCG, but does not involve computations with A^T . On the other hand, BiCGStab is developed so that it is as fast as CGS while avoiding the often irregular convergence behavior of the latter. BiCGStab requires slightly more computations per iteration than BCG and CGS. Finally, QMR attempts to overcome the problems of irregular convergence behavior in BCG. It uses a least squares approach similar to that followed in GMRES, but with a bi-orthogonal basis for the constructed Krylov subspace, and hence, the name. To avoid breakdowns, QMR uses look-ahead techniques, which makes it more robust than BCG. Although it requires a matrix-vector multiplication with the transpose of A , a *transpose-free* version TFQMR is also available.

Preconditioners. The idea behind preconditioning is to accelerate the convergence process of an iterative method by redistributing the eigenvalues of the coefficient matrix so that the difference between the dominant and the subdominant eigenvalue becomes larger without changing the solution vector. Therefore, the need for a preconditioner becomes vital when dealing with ill-conditioned systems.

Now, consider the singular system of linear equations in $Ax = 0$, which can be transformed into the *right-preconditioned* system

$$AM^{-1}(Mx) = 0,$$

or into the *(left-)preconditioned* system

$$M^{-1}Ax = 0,$$

where the *preconditioner matrix* M (also called *preconditioner*) has the property that it is a cheap approximation of A . The more M resembles A , the faster the projection method converges. In fact, the methods of (B)JOR and (B)SOR are preconditioned POWER iterations in which the preconditioning matrices are, respectively, $M_{(B)JOR}$ and $M_{(B)SOR}$, and the POWER method can be viewed as a projection method where subspace information is kept only in a single dimension.

In the case of right-preconditioning, the system $AM^{-1}y = b$ is solved for the unknown $y = Mx$, and the final solution x is obtained through $x = M^{-1}y$. To use right-preconditioning, M should also be chosen so that $M^{-1}v$ is cheap to compute for any arbitrary vector v . In the left-preconditioning case, the system is solved on the basis of imposing the necessary stopping criteria on the *preconditioned residual vector* $r = -M^{-1}Ax$. The matrix M^{-1} need not be formed explicitly, and the preconditioned residual may be computed by solving the system $Mr = -Ax$. Therefore, the preconditioner M should be chosen so that solving any linear system of the form $Mv = u$ for any vector v is cheap.

Various types of preconditioners are considered for MCs [4,19]. Their efficiency is highly dependent on the system to be solved, and it is quite difficult to forecast

which preconditioner is the best for a given problem. In general, incomplete LU (ILU) preconditioners based on dropping nonzero elements smaller than a particular threshold value except those along the diagonal provide effective preconditioners for projection methods in a sequential setting. Recall that A is a negated irreducible singular M-matrix, and it is shown that ILU factorizations (in exact arithmetic) exist for such matrices [20]. When these preconditioners are coupled especially with BiCGStab [7], they provide strong solvers. However, one can also opt for inverse preconditioners, thereby reducing the preconditioning step to a matrix-vector multiplication [21,22], which is quite useful in a parallel setting.

INTRODUCTION

The interest in computational pool is motivated by a variety of factors. The mechanics of pool has long served as a focus of interest for physicists, an interest which has extended naturally to the realm of computer simulation. Realistic and efficient simulators have led to the proliferation of computer pool games. These games include significant computer graphics components, often including human avatar competitors with unique personalities, as well as an element of artificial intelligence to simulate strategic play. There are numerous one-person games available, of differing levels of physical realism.

Though in the context of this article the primary objective is the creation of a computer pool player, we wish to extend our research beyond the scope of billiards. We hope that by researching the best way of making a perfect player we can develop new AI approaches, and possibly contribute to other problems of that nature.

There have been three instances of pool Olympiads where a rival computational pool player competed. The competitions attracted participants from the artificial intelligence community, a pool player representing a challenge for the agent approach. Yet, only 8-ball tournaments were held, and the champions used a Monte Carlo search tree strategy [1–4]. In this article, we develop a complementary approach based on OR techniques,

simulation, dynamic programming (DP), and numerical optimization.

Although the problem we wish to solve is deterministic in nature, subject to the laws of physics, it is so easily influenced by many small factors that it can actually be seen as stochastic. This makes it very hard to create a perfect player, because even if he never misses, the outcome of the game is never predefined.

In this article we will explore the technical challenges of computational pool from an OR point of view. The section titled “The Cue Sports” describes the elements of the cue sports from a human perspective, including some discussion of the aspects of advanced human play. The section titled “Overview of Computational Pool” introduces the several OR aspects to be detailed later on.

The section titled “Modeling Billiards Physics” presents the requirements to produce a simulation model, and the section titled “Modeling Billiards Players” addresses the optimization of a billiards player—this is work in progress.

Future trends are discussed in the section titled “Perspective.”

THE CUE SPORTS

There are many types of cue sports, and many different terminologies and rules that vary with geographical location. For example, the most popular North American pool game is 8-ball, in which there are seven “low” (solid) balls (1–7), seven “high” (striped) balls (9–15) and the 8-ball. The objective is to be the first to sink all balls in one group, and then the 8-ball. Alternately, snooker is probably the most popular cue sport in England, which is played on a larger table and consists of 15 red balls, and 6 of various colors. The balls are smaller than their North American counterparts, and the objective is to accumulate points by alternately sinking a red and then a colored ball, each having a certain value. In France,

a game called *carom* is played, where only three balls are used on a pocket-less table, and the player must attempt to contact both object balls with the cue ball. In the three cushions (“trois bandes” in French) version of carom, the cue ball is required to rebound off three rails before kissing the object ball.

Pool Terminology

The basic elements common to all of these games are as follows. For a much more complete glossary of cue sport terms, see the Wikipedia [5, p. 3] from which we extract the terms relevant to our computational pool study.

- *Cue*. Also known as *cue stick*. A stick, usually around 55–60 in. in length with a tip made of a material such as leather and sometimes with a joint in the middle, which is used to propel billiard balls.
- *Cue Ball*. Also known as *cueball*. The ball in nearly any cue sport, typically white in color, that a player strikes with a cue stick. Sometimes referred to as the *white ball*, *whitey* or *the rock*.
- *Object Ball*. Depending on context it is
 1. any ball that may be legally struck by the cue ball (i.e., any ball-on);
 2. any ball other than the cue ball.
- *Table*. It is the flat playing surface. The table size varies, depending on the game played, but is always rectangular, being twice as long as it is wide. In most games, the table has a pocket in each of the four corners, and one at the centers of each length.
 1. *Bed*: The table is covered in a textured felt (or baize) material, usually of green color, to add a frictional damping effect to the shots.
 2. *Rail*: A rubberized edge running along the inner boundary of the table, to accommodate rebounds following the collision of a ball (cushions in British English).
 3. *Table State*: the position of all balls at rest on the table, ready for the next shot.
- *Shot*. The use of the cue to perform or attempt to perform a particular motion of balls on the table, such as to pocket (pot) an object ball, to achieve a successful carom (cannon), or to play a safety. Different classes of shot type include the following:
 1. *Direct Shot*: A shot where the cue ball hits an object ball, which then reaches a pocket.
 2. *Kick Shot*: A shot in which the cue ball is driven to one or more rails before reaching its intended target—usually an object ball. Often shortened to “kick.”
 3. *Bank Shot*: A shot in which an object ball is driven to one or more rails prior to being pocketed (or in some contexts, prior to reaching its intended target; not necessarily a pocket). Sometimes “bank” is conflated to refer to kick shots as well, and in the United Kingdom it is often called a double.
 4. *Combination Shot*: This is also known as combination or combo. Any shot in which the cue ball contacts an object ball, which in turn hits one or more additional object balls (which in turn may hit yet further object balls) to send the last-hit object ball to an intended place, usually a pocket. In the United Kingdom this is often referred to as a plant.
 5. *Safety Shot*:
 - An intentional defensive shot, the most common goal of which is to leave the opponent either no plausible shot at all, or at least a difficult one.
 - A shot that is called aloud as part of a game’s rules; once invoked, a safety usually allows the player to pocket his or her own object ball without having to shoot again, for strategic purposes. In games such as seven-ball, in which any shot that does not result in a pocketed ball is a foul under some rules, a called safety allows the player to

miss without a foul resulting. A well-played safety may result in a snooker (no direct shot available).

- *Spin*. Rotational motion applied to a ball, especially to the cue ball by the tip of the cue, although if the cue ball is itself rotating it will impart (opposite) spin (in a lesser amount) to a contacted object ball. Types of spin include follow or top spin, bottom or back spin (also known as draw or screw), and left and right side spin, all with widely differing and vital effects. Collectively they are often referred to in American English as “English.”

Specificity of Game Variants

To excel in any pool variant, one has to thoroughly understand the physics, accurately control the cue ball, and plan several shots in advance. However, each variant has its specificity, and the relative weight of those game aspects slightly differs from one variant to another. We examine here four among the most popular games and their specifics.

Games Using Numbered Balls. On the American continent, most pool tables use numbered balls (1–15) in a variety of games. The “official” tables measure $4.5' \times 9'$, but smaller models ($4' \times 8'$ or even $3.5' \times 7'$) are quite common. Hereafter, we briefly discuss three popular game variants using such equipment.

Eight Ball. This is by far the most popular game played on the American continent. However, some of its popularity stems from its use in bars, on coin-operated tables, and the rules of the game reflect this situation.

It is the variant where chance plays a major role, and this is for three main reasons:

- no call is made on the break shot, so any ball pocketed by luck on the break is valid;
- on a foul play, pocketed balls remain in the pockets;
- both players do not play on the same set of balls.

Although not the primary variant in high level human competitions, this has been the variant in the first three computational pool tournaments.

Planning is limited to eight shots before the win. On the other hand, the presence of opponent’s balls may complicate the plan.

Nine Ball. This variant is played with nine balls, and the specifics include the obligation to hit the lowest numbered ball on the table. Thus, planning is somewhat simpler here because of this restriction on which ball is first contacted by the cue ball.

Straight Pool. This is played on similar tables as eight balls pool, but here, any ball has to be called including on the break shot, and balls sunk on a foul are pulled out of the pocket and respotted on the table. Champions achieve runs of several hundred consecutive successful shots. It is clear that this variant requires both clever planning and extreme accuracy. High risk shots involving several rebounds on the rails or with other balls are rare, the players often preferring to resort to defensive shots than to risk losing its turn leaving the opponent with an easy table.

Snooker. Snooker is the most popular variant in the United Kingdom. It is played on a large ($6' \times 12'$) table using 15 red balls and 6 colored balls in addition to the cue ball. The large dimension of the table and the use of slightly smaller balls call for high accuracy. Here again difficult bank, kick or combination shots are often avoided by the frequent use of defensive shots. The name snooker itself refers to the situation where a player has no legal direct shot available.

Carambol. Carom is played on a pocketless table using only three balls, slightly larger than numbered balls though. The game consists in having the cue ball hit the other two balls. In high level competitions, the three cushions variant is often preferred, in which the cue ball has to rebound on three cushions before hitting the second of the other two balls. Obviously, this three cushions variant is extremely demanding in geometric skills,

and the sole difficulty of a single shot almost precludes any form of planning.

In opposition to most pocket billiards variants, the physics model of the collision with the rail is of primary importance here, as is the accurate control of the cue ball. On the other hand, the strategic planning aspect is significantly less important.

OVERVIEW OF COMPUTATIONAL POOL

In this section, we present the three basic building blocks used in a computational billiards player. As we discussed in the section titled “Specificity of Game Variants,” different variants of the game require different balance and specificity in the building blocks.

Physics Simulation

The simulator is required for two aspects in computational pool.

- The first one is to act as a common table and referee in order for the (computer) players to compete. In an ideal world, the simulated game would be indistinguishable from its counterpart as played on a real table. This involves meticulous modeling of the impacts between the cue, balls, rails, and (whenever balls jump) the table. Moreover, the rolling motion of the balls on the cloth must be addressed faithfully.
- The second aspect is a tool on which the AI players rely in order to predict the outcome of a given shot. Here, speed–accuracy trade-offs are expected.

In the first three editions of the computer pool tournaments, the same simulator was used for both uses, some random noise being added on the shots played on the “common table.” As the situation evolves, it is likely that referee simulators will get more and more complex and faithful, yielding high computational costs perhaps no more compatible with the requirements of computational players under limited resources. Ultimately, the games will be played on a real table by robots, and the simulators used by the players will be an integral part of the player’s strategy.

Control of the Cue Ball

When observing a champion at some variant of pocket billiards, two aspects are striking: he/she has mostly easy-looking shots to play, but whenever he/she faces a difficult shot, he/she nevertheless sinks the ball. The first aspect is less spectacular, but is a consequence of his/her accurate repositioning after the impact on the object ball.

Strategic Planning

Another aspect is that the champion takes enlightened decisions with respect to the order in which he/she will sink the balls. In computational pool, this aspect is addressed using some dynamic model of the game aspect.

Among the most evident strategic decisions is the choice to do a so-called *defensive shot*. Instead of aiming to sink some object ball, the player strives to leave the cue ball in such a position that his/her opponent is left with a very difficult situation.

MODELING BILLIARDS PHYSICS

In this section we first summarize the mathematical models that have been developed over the years, going back to Coriolis in 1835. Next we discuss two computer implementations.

Mathematical Models

All variants of billiards and pool games involve a cue, hard spheres, a bed which is a flat surface covered with a cloth, and rail cushions. Spheres slide and roll on the bed, impact on each other as well as on the rails, and the cue gives the initial impact to the cue ball. Thus, we need to model

- cue–cue ball impacts;
- moving balls; mostly, sliding and rolling on the bed, but sometimes “jumping” off the bed for some tiny amount of time, and even sometimes jumping off the table;
- collisions between moving hard spheres, mostly elastic collisions between rigid bodies;

- collisions between hard spheres and cushions on the rails, partly inelastic collisions between a rigid body and a not-so-rigid one (the rail).

All of this is quite delicate to accurately simulate but since the moving bodies are identical spheres, and the bed is planar, the physics equations are rather simple.

The interest in the mathematics of billiards goes back to at least Coriolis [6], and has attracted recent interest as well. In particular, Alciatore, in addition to his book [7], maintains a web site [8] where he posts more mathematically oriented developments including fine-tuning of physical models required to accurately predict the experiments he conducts using high speed video cameras.

Rolling Motion—2D Simplifications. An important observation yields computationally tractable prediction for balls motion on the table. The trajectory of the balls is described by a piecewise quadratic parametric equation. This allows simplification of the collision detection to simultaneous quadratic equations, for which closed-form formulæ are available [9], (Private communication: Sénéchal D. Mouvement d'une boule de billard entre les collisions. 1999) [10]. Moreover, extension to 3D simulation may still be described by piecewise parametric quadratic equations. Therefore, in principle, it is possible to implement a discrete event simulator without using numerical integration. Moreover, since the underlying parametric equations are of the simple piecewise quadratic type, an improved implementation will provide sensitivities and derivatives that are most useful for the optimization aspects to be discussed in the section titled "Optimization Approach."

Ball–Ball Collisions. The balls are almost rigid bodies, and their collision is almost frictionless. The behavior of the object ball and cue ball after the collision are described by the so-called 30° and 90° rules. Actually, slight nonelasticity, small friction, speed, and spin all slightly modify the rules. In Alciatore [8], one can find numerous technical notes providing the fine points of billiards physics.

Ball–Rail Collisions. Those collisions are much more complicated. In most pocket billiards variants though, kick or bank shots are not that frequent, so a simple approach is justified. In three cushions, as the name of the game suggests, those collisions are of prime importance. Larger balls used in carom variants and high energy ball–rail collisions imply that the cushions undergo important deformations, which can no longer be faithfully computed using simple geometric models alone. For instance, in Classic Billiard [11], (Fray J-M. personal communication), a one-person carom game, shots were performed and captured with a camera and in the actual game, interpolation is used to adjust the simulator to replicate the same result. This usage of adjustable variables was necessary as the direct implementation of the physics of the collisions as described in Coriolis [6] yielded different and inaccurate results when compared to real life.

Existing Physically Documented Simulators

While there are many one-person pool playing games, there are few efforts disclosing the actual equations or physical models underlying their simulator; we describe hereafter, two softwares available under open source licenses.

PoolFiz–FastFiz. The first three instances of the pool Olympiads used the PoolFiz simulator [9,10,12], lately replaced by the reimplementations FastFiz [13]. This simulator implements the simplified 2D rolling equations. The actual movement of balls has a spatial component (how the balls move on the table) and a rotational component (how the balls spin). The spin may be represented as rotational velocities around the three main axes, $\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$, $\mathbf{e}_3$ pointing upward and perpendicular to the table's surface. The present implementation neglects any spin in the $\mathbf{e}_3$ axis. The simulator was made available through a common interface to the competitors, who used it to compute their shots. When used as the referee table, some random noise was added to the shot parameters.

In the simulator, the following parameters describe a shot:

- a and b representing the side-spin and top-spin with respect to the cue ball center;
- θ the elevation of the queue stick;
- ϕ the orientation of the queue stick on the table;
- v , the initial speed given to the cue ball.

Billiards. The billiards—techné project [14] adopts a different approach; namely, it uses the ODE open source dynamics engine.

From Smith [15], ODE is an open source, high performance library for simulating rigid body dynamics. It is fully featured, stable, mature, and platform-independent with an

easy-to-use C/C++ API. It has advanced joint types and integrated collision detection with friction. ODE is useful for simulating vehicles, objects in virtual reality environments, and virtual creatures. It is currently used in many computer games, 3D authoring tools, and simulation tools.

As such, physical objects (cue, balls, table bed, table rails, etc.) are described using the ODE interface, and simulated as accurately as ODE allows. No advantage is taken from the simplified nature of perfect spheres rolling on a planar surface. While still in progress, the physics has 3D realism, and care has been taken to validate the

(a)

(b)

Figure 1. Reachable regions. For a simple shot in the upper right corner, we observe the reachable regions for (a) billiards and (b) PoolFiz.

results with high speed camera observations to accurately model the cue ball deflection when using English, an aspect absent from PoolFiz. The approach using ODE has some drawback though: the billiard simulator cannot produce noiseless results since it is built using a fairly sophisticated general purpose physical simulator in which Monte-Carlo techniques are used for improved reliability. There are ways to reduce the random effects but it is impossible, it seems, to completely eliminate randomness.

Simulator Comparison. We illustrate in Fig. 1 the differences in repositioning possibilities of the two simulators. Probably neither is realistic enough to predict repositioning on a real table and further validation is certainly required. Important differences come from the fact that PoolFiz does not take side spin into account on ball–rail collisions, which explains the large area unattainable. Billiards, as compared to PoolFiz, results in less influence of speed on the cue ball deflection after impact with the object ball.

MODELING BILLIARDS PLAYERS

As discussed above, some kind of simulation of the physics is required for the computational player to be able to predict the outcome of a given shot. In this section, we assume such a simulation model is available in the form of a black box. The more accurate the simulator, the more the accurate predictions and planning of the AI player. In the first Olympiads, all the players shared the same simulator, which also acted as table referee. When playing on a robot, or when using a highly accurate simulator, it is expected that different players will use different simulators for their planning.

Two aspects mainly require our attention. A sequence of shots has to be established and thereafter, their execution has to be computed. By a shot, we mean a somewhat generalized shot including repositioning of the cue ball. In the following subsections, we first address the planification of the sequence of shots as modeled by a DP formulation. We also discuss some solution strategies for this

admittedly abstract DP formulation. Actual shots required by the DP planner are then computed using a local optimization model. We cannot avoid the temptation to report our preliminary experience with respect to the local optimization.

Before going further, we must warn that the following modeling assumes the 8-ball game setting. As the model is rather abstract, we expect no fundamental problem in extending this to other pool variants, but of course several minute details will have to be adjusted for other forms of the game.

A Dynamic Programming Formulation

Modeling billiard games is a difficult task and very few known frameworks fit correctly the specific characteristics of these games which are as follows: continuous state and control spaces; actions taken at discrete unknown instants; a specific turn-taking game rule which allows a player to play several times as long as he/she keeps the hand; and stochastic perturbations of moves. Archibald *et al.* [16] have proposed a stochastic game framework valid for finite or repetitive versions of the billiard games and they studied the existence of Nash equilibria associated with stationary Markov strategies. We will first focus on the stochastic control problem, mixing discrete and continuous aspects before introducing the game theoretic ingredients in the model.

Stochastic DP has been introduced to model dynamic discrete processes where random events occur after decisions are applied at each stage of the process. The state space X specifies the position of each ball on the table. It is continuous here but may be discretized to locate balls on the table. The control space $\mathcal{U}$ corresponds to the value of the cue parameters which are adjusted at the beginning of the shot. Each transition is the result of a nonlinear constrained optimization problem that represents the dynamic trajectory of the balls on the table under random perturbations. As seen below, one tries here to minimize the distance of the cue ball from a specified location while maximizing the probability of sinking the object ball. The overall objective function is to maximize the reward of the player (which

is positive when the object ball is sunk in the pocket). The way to model that situation is to add a Boolean variable y_t at each stage which is one when the object ball is sunk. Observe that when $y_t = 0$, the hand is lost and the opponent will inherit the current table. Thus, in difficult situations, a defensive step will try to minimize the opponent's reward. Note also that as long as expectations are used in the stochastic case, a value function can be estimated by backward calculations, starting at an ideal state to pocket the last ball.

Let $\pi = (u_0, \dots, u_{T-1})$ be a feasible policy (series of actions for the states $(s_1, \dots, s_T)$), $P[s' | s, u]$ the probability of going from state s to state s' while taking action u , $R(s)$ the reward for reaching state s . The stochastic program can be stated in the following way (using here a finite-length game):

Maximize

$$\begin{aligned} & \gamma P[y_T = 1 | (u_1, \dots, u_{T-1}; \omega_1, \dots, \omega_{T-1})] \\ & + \sum_t E[R_t(s_t, y_t, \omega_t)] \\ & (s_{t+1}, y_{t+1}) = \operatorname{argmin}_{s(\tau) \in X, u_t \in \mathcal{U}} \\ & \times E[F(s_t, u_t, s(\tau), \bar{s}_t, \omega_t)] \\ & s_t \in X, y_t \in \{0, 1\}, \end{aligned} \quad (1)$$

where $\omega_t \in \Omega_t$ is a random variable with normal distribution and γ is an harmonization factor. The transition step associated with the internal minimization subproblem will be detailed below. It relies on a target position for the cue ball corresponding to state $\bar{s}_t$. The trajectory is represented by $s(\tau)$ where $\tau \in [0, \tau_f]$ is the continuous-time of the motion of the balls, $s_t = s(0)$, $s_{t+1} = s(\tau_f)$.

Let $V^\pi(s)$ now be the optimal expectation of the final reward when applying the sub-policy $(u_t, \dots, u_{T-1})$ from state s_t through the final state.

The equation

$$V^\pi(s) = R(s) + \gamma \sum_{s'} P(s' | s, \pi(s)) V^\pi(s')$$

will be at its optimum if it satisfies the condition

$$V^*(s) = R(s) + \max_{\pi(s)} \sum_{s'} P(s' | s, \pi(s)) V^*(s').$$

Thus, the subpolicy $\pi^* = \{u_t^*, u_{t+1}^*, \dots, u_{T-1}^*\}$ will be optimal for this problem.

For billiards, as stated in Archibald and Shoham [16], we are faced with a continuous-state and continuous-action domain, which introduce further complications.

We find ourselves evaluating an integral instead of a sum

$$V(s) = R(s) + \max_{\pi} \gamma \int_{s'} P(s' | s, \pi(s)) V(s') ds'$$

The optimal strategy of discrete dynamic programs is commonly solved by performing *backward computations* from the final state back to the current state. We will discuss that strategy below, after saying a few words about the underlying game theoretic issues.

Game Issues

Let us consider first, the simpler situation of a finite game (such as 8-ball). It is not easy to analyze the general strategy which interprets a defensive shot as the one which will *leave a difficult table to the adversary, thus expecting to take back the hand later to finish the game*. This means indeed that the final profit associated with $P[y_T = 1]$ is still valid. Nevertheless, we should here pull from a possible table at stage t to an unknown table at $t + q$ where q is the number of estimated shots left to the opponent. We refer to Archibald *et al.* [17] for an interesting AI point of view of the strategic issues.

Solution Strategies for the DP Model

The general problem of finding $V^\pi(s)$ for a deterministic problem may be quite complex by itself, and often becomes intractable as more variables come into play. It is even worst for a problem with a continuous state and action space. However, in our case, we can benefit from the knowledge we have of the game we are solving and extract important information to narrow our search to a limited number of action–state space combinations.

Assumption 1. $y_t = 1, t = 1, \dots, T$.

Assumption 1 corresponds to the so-called *win-off-the-break* winning sequence. The optimal value is hence the expected sum of remaining rewards (for each shot) to get

through the game. The way to cope with the fact that the success of the game is now deterministic is to add a *technical reward* to an easier shot, or equivalently, to a better position for the cue ball on a given table.

Assumption 2. The cue and object balls are the only balls expected to move.

With Assumption 2, we get a direct estimate of the future positions of all future object balls. The player strategy corresponds to the “optimistic planner” described in Archibald *et al.* [17].

Observation. Later, we will naturally relax Assumption 2 to authorize collisions with other balls (and with the rails). Then, a new question will arise: should we consider only side collisions due to the trajectory of the cue and object balls, or should we include different shots aiming at repositioning the cue ball so that a collision happens with another ball (or a cluster of dangerously close balls)? That latter situation is now under study. The skill model to compute the optimal trajectory of the balls will here be much more intricate as it will involve elastic collisions and singularities [18].

Back to the stochastic dynamic program, assuming Assumptions 1 and 2, we will now proceed backward to estimate the optimal value of a given table. We may start with the last table which can be modeled as the current table where we want to sink, not the current object ball, but the one which should be sunk at the last shot. To compute all $V^\pi(s_{T-1})$, we must compute the pocket angle for each of the remaining balls and then perform an inverse step to position the cue ball in all feasible states at $t = T - 1$. The optimization black box will be very useful as it already works with an estimate $\bar{s}_t$ of the desired repositioning state.

Observation. The curse of dimensionality will probably make these computations cumbersome and time-consuming if T is large, but we can begin testing increasingly complex situations setting $T = 2, 3, \dots$ which can be easily adapted from the general case.

Optimization Approach. Here, we describe briefly the minimization subproblem associated with the transition step at stage t as defined in model 1.

Suppose we are using the black box simulator described earlier, with the action variable u_t being the finite-dimensional vector of the five parameters a, b, θ, ϕ , and v . The trajectories $s(\tau)$ of the balls moving on the table at a given shot depend thus on the initial state $s(0) = s_t$ and on u_t , the latter being perturbed by the random variable ω_t .

To compute an optimal action u_t , we minimize a least-square function associated with the desired reposition $\bar{s}_t$ of the cue ball on the table and the desired sinking of the object ball. The objective function can thus be modeled in the following way:

$$\begin{aligned} F(s(\tau), u_t, \omega_t) &= \|s(\tau_f) - \bar{s}_t\|^2 \\ \text{subject to } s(\tau) &= \psi(s_t, u_t, \omega_t) \\ y &= 1 \text{ if } s_{obj}(\tau) = \bar{p} \text{ for } \tau \in [0, \tau_f], \end{aligned}$$

where ψ is the dynamic transition function associated with the simulator, s_{obj} is the component of s associated with the object ball, and $\bar{p}$ is the component of $\bar{s}_t$ associated with the pocket. The solution of the minimization subproblem will then give $s_{t+1} = s(\tau_f)$ with the corresponding value of y updating y_{t+1} . In the stochastic case, the function is replaced by an expectation value computed from the known distribution of the noise on the action variables.

The detailed formulation of the minimization problem and its resolution by an adaptation of Powell’s derivative-free Quasi-Newton method [19] can be found in Landry and Dusault [20].

Value of Billiards. In a general matter, the difficulty of executing a shot on a billiard table is defined by two aspects: (i) the distance between the cue ball, object ball and pocket, and (ii) the angle at which the cue ball will hit the object ball. Other factors, such as the closeness of the cue ball to the rails or other balls partially blocking the path of the shot, also come into play. However, we can still get a fair estimate of a shot difficulty by using the first two aspects described. A real and precise

Figure 2. Shot difficulty: The distance of the cue ball to the object ball, of the object ball to the pocket, the cut angle, and the angle with the pocket all influence the difficulty of a shot, proportional to the admissible error with respect to the “perfect” shot that will sink the object ball right in the center of the pocket.

difficulty coefficient is almost impossible to compute since it will not only rely on the percentage of success of the computed shot, but also on the impact of this shot for the cue ball repositioning.

As shown in Fig. 2, both the angle and distance factor result in a calculable angle θ for the shot difficulty. A shot aimed at the center of this angle should normally result in the best success percentage for this shot.

Once we have computed this coefficient, we can use it to evaluate any given table state, simply by taking the maximum value of all the available shots for a given cue ball position. If we now divide our billiard table into a 50×100 grid, we can take the value of $\max_{i=0}^n \theta_i$ at each of these points and come up with the best repositioning targets for the next shots by removing each time the ball we would be aiming for (since we assume it will be pocketed).

However, this first and seemingly logical evaluation of a billiard table state is not necessarily applicable to all variants of the game, and does not for the moment take into

account defensive shots. It does however, provide an estimation of table state values for offensive play.

Results. To show the effectiveness of the optimization model discussed in this article, we ran some tests on randomly generated table states and computed possible shots using local and global optimization libraries. We show here only two of the best performers we tested for the sake of brevity. BOBYQA was selected since it was the fastest of the approaches tested and DIRECT-L was the most successful with the best solutions found. Both approaches were implemented using the NLOpt library [21]. BOBYQA, a local optimization method by James and Powell [19] was tested with five different starting points, distributed over the possible shot parameters. DIRECT-L, a global optimization method by Jones *et al.* [22], was tested with only one starting point.

A total of 1000 random table states were generated and each possible shots on these tables were explored, thus coming close to a total of 20,000 various shots which

Table 1. Results of 19930 Different Shots Computed with the Local Optimization Method BOBYQA and Global Optimization Method DIRECT-L

	Success (%)	Average time (s)	Average time success shots (s)	Average Distance (m)
<i>DIRECT-L</i>				
Direct shots (4310)	97.21	0.37	0.38	0.15
Kick shots (6950)	95.59	0.78	0.78	0.19
Bank shots (7520)	72.0	0.85	0.99	0.59
Combination shots (1150)	85.13	2.02	2.09	0.4 m
<i>BOBYQA</i>				
Direct shots (4310)	96.10	0.08	0.07	0.34
Kick shots (6950)	88.21	0.13	0.12	0.43
Bank shots (7520)	35.45	0.12	0.16	0.68
Combination shots (1150)	46.00	0.31	0.34	0.62

Average times (sec) are displayed for all shots, as well as for successful shots. The average distance (m) is the distance from the repositioning target.

were computed using both libraries. Each of these shots represents a combination of an object ball, an aimed pocket, a cue ball, and a repositioning target. As can be seen in Table 1, types of shots included direct, kick, bank, and combine shots.

The local optimization method, even though launched five times with various starting points, gets a slightly lower success percentage for bank and combine shots. The DIRECT-L, however, being a more global approach, achieves better results but at a higher cost in calls to the simulator. What these results actually show us is that we can obtain satisfying results to compute single shots with very few calculations. The trade-off between the solution’s quality and the computation time needs to be carefully studied to achieve the best compromise, but this will also vary with respect to the variant of game played. It should also be noted that in case a solution is not found for a given shot, it is usually because it is not possible because of other balls or rails restricting the queue motion. Thus, a global method may be able to find a solution by doing a spectacular shot but one that is not very reliable when played on a stochastic system. Further testing is needed to adapt the search criteria to the type of game played, and the level of noise present in the simulator.

PERSPECTIVE

We described a new application field of computational billiard and proposed a method of approaching the problem from an OR perspective. The field is really emerging, and much is to be expected in the near future. However, the ultimate goal to have a computer robot challenge human champions still appears quite remote. We did not discuss the robotic aspect of this challenge, but it should be clear that good progress has been made on the computational aspect, and that much remains to be done in this new field.

From an OR-specific point of view, we have described a stochastic DP framework to model an optimal strategy of a generic billiard player in the presence of noise. The key contribution is an improved estimation of the table value at some stage that takes into consideration the expectation of the difficulty to complete a sequence of winning shots and not only the current one. The present modeling is coherent with the conclusions of Archibald *et al.* [17] who state that “strategic skill” is decisive whenever “the execution skill” is imperfect.

On the other hand, we have presented an improved player simulator based on an accurate optimization tool to drive the cue ball trajectory toward the desired spot with the “best” table value. Numerical simulations on repeated launching of 8-ball games were

performed with relative success, including indirect shots like bank and combine shots, confirming the robustness of our player.

Current work aims at improving the player skill to cope with more realistic situations including the precise modeling of elastic collisions with banks and the breaking of clusters of balls.

Finally, the introduction of defensive strategies to take into consideration the game theoretical aspects will be the direction of further studies. It is indeed evident that the development of future competitions between virtual players controlling robots acting on a real table will progressively increase the level of noise effects, thus making more crucial the improvement of the “strategic skill” of the players.

Acknowledgments

We are grateful to François Gaumond and Benoit Hamelin for their careful reading of the manuscript and useful comments and François Gaumond’s work on the Billiards–PoolFiz interface. We also wish to thank the referees for their constructive suggestions.

CONCEPTS OF NETWORK RELIABILITY

CHARLES J. COLBOURN
SCIDSE, Arizona State
University, Tempe,
Arizona

THE BASIC MODEL

The likelihood that a network supports an acceptable level of operation is a key metric in network design and network performance. To quantify this, one must develop a precise model of the network, the causes of failures, and the meaning of network operation. Then, depending upon the specification of each, a quantitative measure of the ability of the network to operate is developed.

In this short overview, basic concepts are developed but no attempt is made to capture the wide variety of definitions, algorithms, and theories that have been developed. In general, for more in-depth expositions, see Refs 1–3 for network models, Refs 4–6 for computational complexity results, Refs 1, 7, 8 for Monte Carlo methods, Refs 9–11 for Boolean methods, and Refs 1, 12 for combinatorial bounds using complexes. A limited number of additional references are used in the text to follow.

In order to motivate the topic, let us consider a simple network design example. Seven nodes are to be connected by bidirectional communication links. Although six links suffice to provide at least one path connecting each pair of nodes, one or more of the links chosen may fail. If only six links are constructed, then a single failure results in at least one pair of nodes having no operating communication path. Of course, if network cost is not a substantial concern, we could simply construct all $21 = \binom{7}{2}$ possible links, and then no failure of fewer than six links can cause two nodes to be unable to communicate.

Network reliability is concerned with balancing the desire to limit network construction cost and the need for continued operation in the event of component failure. In our toy example, suppose that we have determined that any 10 links can be constructed. Figure 1 shows three possible ways to select the links.

The basic question is: Which one is “better”? The answer naturally depends on what we expect the network to do. If our goal is to ensure that node 2 can reach node 3, the failure of a single link cannot prevent this. In the first network, there is no way for two links to fail, so no path remains from node 2 to node 3. However, in the second, there is exactly one way. On this basis, we might prefer the first network to the second. If, on the other hand, our goal is to ensure every node can communicate with every other node, again no single link failure can prevent this. However, in the first network there are four ways to remove a pair of links to disrupt some connection, while in the second there are only three. On this basis we might prefer the second network to the first. But for both operations, we might prefer the third choice among these.

Naturally, arguments of this type are both imprecise and overly simple. A genuine application would require a substantial amount of information not provided in this toy example. Here, our objective is to make the concepts involved, including the model, the network operation, and the measures of network reliability, precise. With those in hand, one can choose a reliable network design from a huge variety of candidates typically available, and evaluate how likely it is to support the specified operation.

Network Model

Network reliability has been concerned primarily with networks for digital communication. A network begins as a collection of *nodes*, each representing a site that originates, terminates, or forwards network traffic. Although a wide variety of technologies

Figure 1. Three networks with seven nodes and 10 links.

are available to support communication, at the most basic level each provides a *link* that permits communication among a specified set of nodes. Links may be *unidirectional*, supporting traffic from one node to others but not supporting return traffic; or *bidirectional*, supporting traffic in both directions between nodes. Links may be *point to point*, supporting traffic between exactly two nodes; *multipoint*, supporting traffic among a collection consisting of some but not all nodes; or *broadcast*, permitting communication among all nodes. Traditionally, network reliability has been concerned with point-to-point links; this is used for illustration here, but the concepts apply more generally.

A *graph* is a set V of elements called *vertices*, and a collection E of pairs of vertices. Each $e = \{x, y\} \in E$ is an *edge* of the graph. When nodes of a network are represented as vertices, a bidirectional link can be represented as an edge. In this way, graphs serve as very simple models of networks. In a similar way, a unidirectional link can be represented as an ordered pair of vertices, forming a *directed edge* or *arc*. When E consists solely of arcs, $G = (V, E)$ is a *directed graph* or *digraph*. When E contains both undirected and directed edges, it is a *mixed graph*.

Graphs, digraphs, and mixed graphs all serve to model various types of point-to-point networks. However, these alone are insufficient to model network operation and network failure in general.

Node and Link Characteristics

In assessing the operational status of a network, requirements and characteristics for nodes and links may play a central role. For example, links may have a capacity, delay, installation cost, transmission cost, distance, or the like; nodes may have an installation

cost, capacity, rate, and the like. Basic graph models are often augmented by equipping each vertex and each edge with measures of these and other characteristics; to do so, the graph model (V, E) of a network is extended by adjoining functions to specify the relevant characteristics of each vertex and each edge. These characteristics may be a deterministic, fixed property of each node or link, or may be stochastic in nature. The nature of these in turn impacts the notion of network operation.

Network Operation

In the reliability context, the ultimate goal of network modeling is to determine the ability of the network to provide an acceptable level of service. There are numerous ways to quantify network service, and to set thresholds to determine a level at which it is acceptable. For example, for a specification of point-to-point traffic requirements, acceptable service may mean that every pair of nodes can simultaneously be allocated communication paths so that all pairs can communicate an amount at least as large as is dictated by the traffic requirements.

In practical settings, acceptable network service may be a complex function of node and link characteristics. Nevertheless, studies of network reliability have focused primarily on very simple metrics based on connectivity. A requirement for point-to-point traffic to be carried from a node s to a node t is that there is a sequence of nodes starting with s and ending with t , each connected to the next by an edge. This is a *path* in the graph. The mere existence of a path from s to t may not suffice to deliver an acceptable level of service, but the absence of such a path almost surely prevents it. A more complex model that accounts for many characteristics of each node and link on the path, and also its interactions

with other paths, may be much more accurate than one that simply considers the presence or absence of a path. Nevertheless, it is almost certainly much harder to analyze in a useful manner. In the trade-off between the accuracy of the model and the difficulty of analyzing it, most network reliability models err on the side of keeping the model quite simple by focusing just on connectivity. While this may paint an overly optimistic picture of the network's ability to support specific network functions if used too generally, it does address the question of whether the network structure itself can be expected to provide the connections needed; whether these connections are large enough, fast enough, and cheap enough is another matter.

With this in mind, three basic operations are most often considered for bidirectional links. In the *all-terminal* operation, every pair of nodes must be connected; in other words, there is a subset of the edges that are operating which, for each pair of vertices, provides a path between them. Equivalently, one requires that the operating edges contain a *spanning tree* of the graph, which is a connected subgraph in which the number of edges is precisely one less than the number of vertices. In the *two-terminal* operation, two specified nodes s and t must be connected by a path of operating edges. Intermediate between these is the *k-terminal* operation, in which the nodes of some specified set $K \subseteq V$ of size k all lie in the same connected component induced by the operating edges. Variants of these operations can be defined for digraphs and mixed graphs as well.

Causes of Failure

Network design is concerned with provisioning a network with sufficient resources to support its operation. However, failure or degradation of components may result in the inability to support a level of operation that would be possible in the absence of such failures. What causes nodes and links to fail? At one extreme, an intelligent and powerful adversary may destroy certain components selectively in order to disrupt the network. Given sufficient power and resources, such an adversary can destroy the entire network,

and there is no design to overcome this. However, some network structures require more resources on the part of the adversary than do others. Design to make adversarial attack unduly costly is the province of *deterministic network reliability* or *network vulnerability*. At the other extreme, failures may result from random, independent events such as component wear-out. Such events affect nodes and links independently of one another, and their probability of occurrence within a specified time frame can sometimes be estimated from historical data concerning similar nodes or links. In this case, the metric of interest is the probability that a network can support a specified operation when its nodes and links fail independently with known probabilities; this is most frequently called the *network reliability* problem, although *probabilistic* or *stochastic network reliability* might be more accurate.

Neither extreme typifies the behavior of most networks. Indeed, failures often arise from environmental causes, such as power failures or traffic congestion, that disrupt links and nodes in a small geographic region. While such failure events can also be assigned an estimated probability of occurrence, they do not act independently. Rather, they induce a statistical dependence affecting the joint probabilities of link and node failures. This leads to *network reliability with dependent failures*.

Despite the many ways that such dependences arise in the real-world, the focus has been on network vulnerability and network reliability. The reasons for this are manifold. While historical data can often serve to estimate link and node failure probabilities prior to designing a network, dependences are by their very nature a product of the environment in which the network is deployed. Determining the possible failure causes, understanding their dependences, and estimating the likelihoods of each and of simultaneous occurrences of them are each challenging problems. Consequently, one assumes that the worst possible dependences may arise that lead to network vulnerability and deterministic measures, or one assumes that the dependences are relatively inconsequential and that a sufficiently accurate

model is obtained by assuming statistical independence.

When neither assumption is reasonable, *fault-tree analysis* [13] and *binary decision diagrams* [14] can be used to model the dependences. Both require a characterization of causes of failures, which is often not readily available.

Network States and Probabilities

Once a particular network operation is selected, and components are identified whose operation or failure impacts the network operation, a *state* of the network is an assignment of “operational” or “failed” to each of the components. Each state is itself either able to support the desired network operation or is not able to, and is *operational* or *failed* accordingly. Fundamentally, the concern of network reliability is to assess the likelihood that the network is in a state that is operational either at some point in time or during an interval of time in which the operation is to be conducted. Naturally, this depends critically on the causes of component failure. However, when components fail as a result of random, independent events, one can determine the probability that a network is in a specific state S . This is done by employing the probability, for each component subject to failure, that the component has the status indicated in state S . Then, as a consequence of independence, one multiplies all of these component probabilities to determine the probability that the network is in state S .

For this reason, reliability in the context of random, independent failure events has been a primary focus of research in the area, and we shall consider only that situation hereafter.

Network Reliability, Resilience, and Performability

For a given network operation, the *network reliability* can be defined precisely as the sum, over all operational network states, of the probability that the network is in that state. This can be determined by a *complete state enumeration* in which all states are listed; failed states are removed from the listing; probabilities of occurrence are

computed for each operational state; and these probabilities are summed to yield the reliability. In particular, when the operation chosen is all-terminal, k -terminal, or two-terminal, this yields the standard definitions of *all-terminal*, *k-terminal*, or *two-terminal reliability*.

Many related notions have been considered, but we mention only three. The models treated here concern components with two states and network operation with two states. Treating components and networks with more than two states yields *multistate reliability*, to which many of the concepts discussed here readily extend. When components each have two states but the network has possibly many, in addition to the probability of occurrence of each state, one can employ a *performance metric* to specify to what degree the network state supports the network operation. Typically, one chooses a numerical performance metric for which larger values indicate “better” performance. Then, the *expected performance*, or *performability*, of the network is the sum, over all states, of the product of the performance metric of that state with the probability of being in that state. (See Ref. 15, for example.) Standard reliability measures are recovered by specifying that the performance metric itself takes on only value 0 for failed, and 1 for operational.

A third related notion concerns network design to support many network operations. For example, on a network $G = (V, E)$, each choice of $\{x, y\} \subseteq V$ underlies a different two-terminal network operation. Yet, one may wish to support *all* two-terminal operations and not just one. In this case, one can consider the average reliability taken over all network operations of interest, with each selected uniformly at random. In this context, *two-terminal resilience* is the average two-terminal reliability, and *k-terminal resilience* is the average k -terminal reliability [16]. While this appears to involve many reliability measures, one for each operation of interest, it is easily recast as a performability measure as follows. Suppose that there are μ types of network operation. Then for state S , let $\omega(S)$ be the number of these operations supported in state S . Define a

performance metric for state S as $\omega(S)/\mu$. Then the resulting performability measure is exactly the average reliability over the chosen network operations.

In this manner, many reliability, performability, and resilience measures can all be viewed in a single, consistent framework.

STATE-BASED MODELS

Now we proceed more formally, focusing on reliability measures. Let $e_1, \dots, e_m$ be a set of components, which we take to be edges of a graph G . Let $p_1, \dots, p_m$ be probabilities, so that p_i is the probability that e_i is operational. A state of the network is specified as a binary vector of length m , $\Phi = (\phi_1, \dots, \phi_m)$, where ϕ_i is 1 when e_i is operational and 0 when not. Equivalently, a state is a subset of $\{1, \dots, m\}$ that contains the indices of the operating components; subsets and their characteristic vectors are used interchangeably to denote states. The set of all states is therefore just the powerset of $\{1, \dots, m\}$, that is, $2^{\{1, \dots, m\}}$. Assuming independence, the probability $\Pr[\Phi]$ that the network is in state Φ is given by $\prod_{i=1}^m (p_i \phi_i + (1 - p_i)(1 - \phi_i))$.

Any (two-state) network operation can be represented as a subset of the set of all states, $\mathcal{P} \subseteq 2^{\{1, \dots, m\}}$. Members of $\mathcal{P}$ are *pathsets*. Then the reliability $\text{Rel}(G, \mathcal{P})$ is $\sum_{\Phi \in \mathcal{P}} \Pr[\Phi]$. Of course, one could equally well define reliability in terms of failed states. Letting $\bar{\mathcal{P}} = 2^{\{1, \dots, m\}} \setminus \mathcal{P}$, one has that $\text{Rel}(G, \mathcal{P}) = 1 - \sum_{\Phi \in \bar{\mathcal{P}}} \Pr[\Phi]$. One can also define $\mathcal{C} = \{X : X = \{1, \dots, m\} \setminus Y, Y \in \bar{\mathcal{P}}\}$. A subset of $\{1, \dots, m\}$ appears in $\mathcal{C}$ exactly when the *failure* of all edges in the subset leads to a failed state of the network; hence members of $\mathcal{C}$ are *cutsets*.

Although these state-based definitions of reliability provide a precise definition, the obvious algorithm to compute them involves the consideration of 2^m states, and is infeasible for large networks. It is therefore natural to ask whether more sophisticated methods can provide algorithms to compute reliability in time bounded by a function whose growth rate is less than exponential in m . We treat the (mostly negative) results next, and later address methods for circumventing the lack of efficient algorithms.

Computational Complexity

Computational complexity addresses the resources such as computational time or space needed to solve specific problems. Although a specific problem is given, we are concerned with methods that solve *each* instance of the problem, no matter how large, in a finite amount of time. The *size* of an instance is usually specified to be the amount of space needed to represent the instance using a finite alphabet. Let $T(n)$ represent the largest amount of time taken for an algorithm to solve an instance of size n (so that we are concerned with *worst case complexity*). Often, $T(n)$ is a complicated function whose exact values are not known. Nevertheless, we can make a clear distinction between functions that grow faster than any polynomial function of n and those that are bounded by some fixed polynomial. Algorithms whose running times are bounded by a polynomial are *efficient* or *polynomial-time* algorithms, and much of the design of algorithms is concerned with finding efficient algorithms for specific problems.

We face two difficult issues in exploring reliability. First, what is the size of the input? To specify an n -vertex, m -edge graph, it suffices to employ $O(m \log n)$ bits. However, to specify the network operation of concern, we must decide whether to represent it explicitly (for example, by providing $\mathcal{P}$) or implicitly (for example, by saying that for two vertices s and t the state contains an s, t -path). If we adopt an explicit representation, the size of the input alone can be $O(2^m)$, and hence the input is by itself exponential in the size of the graph, and any hope for an algorithm whose running time is efficient (in the size of the network) vanishes. Therefore, essentially all effort to date concerns reliability measures for which the description of the network operation requires $O(m \log n)$ space. We make this restriction here, but note that in the process we still consider all-terminal, k -terminal, and two-terminal reliability.

The second issue that we face is how to proceed when the best current efforts have failed to produce an efficient algorithm. Naturally, we would like to establish that none exists. However, known techniques for establishing lower bounds on the complexity of

problems are much weaker in general than those for establishing upper bounds. While a single algorithm suffices to establish an upper bound, one must establish that none of the possible algorithms is efficient in order to establish the desired lower bound. Nevertheless, machinery is well developed for providing compelling evidence that a problem admits no efficient algorithm, through the theory of NP-hardness and #P-hardness. The class #P contains counting problems, while NP contains decision (“yes”/“no”) problems; all #P-hard problems are NP-hard [17]. NP-hardness is usually taken to indicate that no efficient algorithm exists for the problem.

For network reliability, many problems have been shown to be #P-hard, including all-terminal, two-terminal, and k -terminal reliability. Although these results effectively close off the possibility of certain types of algorithms, other avenues open. While the complexity results indicate that there are *some* hard instances of these reliability problems, it does not preclude the possibility that an algorithm exists that solves “most” instances efficiently, which with luck may include most instances arising in practice. Moreover, two exponential time algorithms can exhibit quite different execution times on the same instance, and therefore practical improvements on complete state enumeration are of significant concern.

It is also sensible to relax the requirements of the problem. While network reliability is a precise numerical quantity (once the component probabilities and network operation are specified), numerous assumptions and simplifications led to its definition. Therefore, one might consider obtaining a point estimate of the reliability, along with confidence intervals, using a Monte Carlo strategy. For certain environments, the probabilistic guarantee obtained for the reliability may be insufficient. Nevertheless, in these cases obtaining absolute lower and upper bounds may suffice to ascertain whether a particular network design meets, or does not meet, application requirements. Finally, one might characterize the networks that arise in practice; it may be possible that they share a network structure that admits an efficient algorithm, despite

the expectation that arbitrary network structures do not. Each of these avenues has been pursued extensively; in the remainder, we provide a brief outline of each.

Pivotal Decomposition or Factoring

Suppose that $\mathcal{P}$ defines a set of pathsets, and that e is a component (edge) of the network in question. Define the *deletion* $\mathcal{P} \setminus e$ to be the set $\{P : e \notin P \in \mathcal{P}\}$, that is, the collection of all pathsets that do not contain e . Define the *contraction* $\mathcal{P}/e$ to be the set $\{P \setminus \{e\} : e \in P \in \mathcal{P}\}$, that is, the collection of all pathsets that do contain e , with e then removed. For a graph G with an edge e , $G \setminus e$ is the result of deleting edge e from G , while G/e is the result of identifying the two endnodes of e and then removing the edge e . With this notation and assuming independence, it follows that

$$\begin{aligned} \text{Rel}(G, \mathcal{P}) &= (1 - p_e) \cdot \text{Rel}(G \setminus e, \mathcal{P} \setminus e) \\ &\quad + p_e \cdot \text{Rel}(G/e, \mathcal{P}/e). \end{aligned}$$

This is the *factoring formula*, sometimes called *pivotal decomposition* in which e is the *pivotal element*. When carried through until no edge remains, this effectively reproduces complete state enumeration. However, it forms the basis for many useful algorithms. The primary reason is that, while G may have a complex structure, after certain deletions and contractions the resulting graph may have a simpler structure whose reliability can be calculated by more direct methods. When this occurs, there is no need to apply factoring further to the intermediate graph. In a similar vein, although we may not be able to apply reliability-preserving transformations to simplify the graph itself, deletions and/or contractions may lead to the possibility of applying them at intermediate stages.

Perhaps the greatest benefit of factoring is that, except for independence, no assumptions are required about the graph or the model of network operation.

Transformations and Reductions

All methods discussed are quite sensitive to the size of the instance, that is, to the number

of edges. Hence techniques to remove edges when possible are of critical concern. The easiest case is when an edge e is *irrelevant*, in that no pathset contains e ; in this case, $\text{Rel}(G, \mathcal{P}) = \text{Rel}(G \setminus e, \mathcal{P} \setminus e)$. For all-terminal, k -terminal, and two-terminal reliability, determining when an edge is irrelevant is straightforward; however, for general notions of network operation, this determination can itself be NP-hard. When an edge e appears in every pathset, e is *mandatory*, and $\text{Rel}(G, \mathcal{P}) = p_e \cdot \text{Rel}(G/e, \mathcal{P}/e)$.

Suppose now that every edge is neither irrelevant nor mandatory. Two edges e_1 and e_2 are *complements* if, for every $P \in \mathcal{P}$, either $\{e_1, e_2\} \in P$ or P contains neither. A reliability-preserving reduction is then to contract e_2 , and replace the operation probability of e_1 by $p_{e_1}p_{e_2}$. A specific case for graphs arises when e_1 and e_2 share a node that is not a target; then this is a *series reduction*. Two edges e_1 and e_2 are *substitutes* when for every $P \in 2^{\{3, \dots, m\}}$, $P \cup \{e_1\} \in \mathcal{P}$ if and only if $P \cup \{e_2\} \in \mathcal{P}$. A reliability-preserving reduction is then to delete e_2 , and replace the operation probability of e_1 by $1 - (1 - p_{e_1})(1 - p_{e_2})$. A specific case for graphs arises when e_1 and e_2 both connect the same two nodes; then this is a *parallel reduction*.

Essentially, all methods reduce the graph by treating irrelevant and mandatory edges, and by series and parallel reductions. However, a wide variety of other reductions have been examined as well.

Approximation: Monte Carlo Methods

Despite simplifying reductions, often the number of states is too large to enumerate. When this occurs, an estimate of the reliability can be obtained by selecting states at random, and determining whether that state is operational. This forms the basis for *crude Monte Carlo* algorithms. Indeed, when in each trial a network state is chosen by selecting each component e to operate with probability p_e , an unbiased estimate of the reliability is simply the ratio of the number of trials leading to operating network states to the number of trials performed. Crude Monte Carlo can be effective for small networks, particularly when the network operation of concern does not exhibit structure that can

be exploited to limit the sampling needed. More sophisticated Monte Carlo techniques employ the structure of operational and failed states to reduce the number of samples. The goal of a Monte Carlo method is to produce an unbiased estimator of the reliability, and to produce useful statistical confidence intervals on this estimate within a “small” number of trials.

Most Probable States

Of particular practical concern are networks in which every edge has an operation probability close to 1. In this setting, crude Monte Carlo tends to select operational network states repeatedly, only very rarely encountering a failed network state. Consequently, numerous trials are typically needed to produce useful confidence intervals. Indeed, the same network state is often generated repeatedly. To avoid this, one could sample the network states without replacement, by maintaining a library of states already encountered. An advantage is that one can establish not just a confidence interval, but also *absolute* lower and upper bounds on the reliability, by accumulating the probabilities of the failed and operational states encountered thus far. But the disadvantage is that there is no particular structure in the states so far encountered, because they have been randomly generated.

Instead, *most probable state* methods abandon the search for a point estimate and confidence interval, and instead enumerate states in nonincreasing order of probability of occurrence [18]. The key is to maintain a data structure from which the next most probable state to be generated can be easily determined without explicitly examining states already generated. Improvements are possible when the operational status of a class of network states can be determined from the operational state of a single state.

PATH- AND CUT-BASED METHODS

When the network operation is arbitrary, every method essentially must either enumerate all states (perhaps in a certain order),

or sample from all states, because the operational status of one network state cannot determine the operational status of another. In many practical environments, however, this is not the case at all! Consider a set of pathsets $\mathcal{P}$, and a particular pathset $P \in \mathcal{P}$. When $e \notin P$, can it happen that $P \cup \{e\} \notin \mathcal{P}$? If this occurs, it indicates that, when the components of P operate and the remaining components fail, the network operates; however, when the state of e changes from failed to operating, the state of the network changes from operating to failed. In all-, k -, and two-terminal reliability, this cannot occur.

Coherence of $\mathcal{P}$ is the property that whenever $P \in \mathcal{P}$ and $P \subseteq P'$, we find that $P' \in \mathcal{P}$. Equivalently, if $\mathcal{C}$ is the set of cutsets, then whenever $C \in \mathcal{C}$ and $C \subseteq C'$, we find that $C' \in \mathcal{C}$. Not all natural reliability problems are coherent. For example, if in a graph we take the vertices as the components, and the network operation is that “all operating vertices are connected,” then when only one vertex operates the network is operational, but when two operate, the network is operational only when the two are connected by an edge. Nevertheless, the focus of efforts on reliability has been on coherent problems.

For coherent problems, rather than considering all states, all pathsets, or all cutsets, one can consider much smaller sets of states. A *minpath* is a pathset $P \in \mathcal{P}$ for which there is no $e \in P$ with $P \setminus \{e\} \in \mathcal{P}$. The notation $\mathcal{MP}$ is used for the set of all minpaths. Similarly, a *mincut* is a cutset $C \in \mathcal{C}$ for which there is no $e \in C$ with $C \setminus \{e\} \in \mathcal{C}$. The notation $\mathcal{MC}$ is used for the set of all mincuts. Knowing $\mathcal{MP}$, one can recover $\mathcal{P}$ by taking all supersets of the minpaths; the same holds for cutsets. For example, with all-terminal reliability a minpath is a spanning tree, and all connected subgraphs can be found by adding zero or more edges to a spanning tree.

Boolean Techniques

Let $e_1, \dots, e_m$ be a set of components and $x_1, \dots, x_m$ be the events that they operate. For a particular minpath $P \in \mathcal{MP}$, the event that all components of P operate is $\bigwedge_{e_i \in P} x_i$. Then the event that the network operates is just $\bigvee_{P \in \mathcal{MP}} \bigwedge_{e_i \in P} x_i$. By the same token, for a particular mincut $C \in \mathcal{MC}$, the event that all

components of C fail is $\bigwedge_{e_i \in C} \bar{x}_i$, and the event of network operation is $\bigvee_{C \in \mathcal{MC}} \bigwedge_{e_i \in C} \bar{x}_i$.

While each provides a simple Boolean expression for reliability in terms of minpaths or mincuts, the computational difficulty arises from the fact that, for two minpaths P_1 and P_2 , the events $\bigwedge_{e_i \in P_1} x_i$ and $\bigwedge_{e_i \in P_2} x_i$ are independent only when P_1 and P_2 share no components. Express the event that at least one of the pathsets P_1 and P_2 operate by $(\bigwedge_{e_i \in P_1} x_i) \vee ((\bigwedge_{e_i \in P_1} \bar{x}_i) \wedge (\bigwedge_{e_i \in P_2} x_i))$. The two events in the disjunction are mutually exclusive, or *disjoint*. Hence the probability of either occurring is just the sum of the probabilities of each occurring individually. Extending this to many minpaths (or mincuts), network reliability can be written as a disjunction of disjoint events. In the process, however, expressions of the form $E = (\bigwedge_{e_i \in P_j} x_i) \wedge \bigwedge_{\ell=1}^{j-1} (\bigwedge_{e_i \in P_\ell} \bar{x}_i)$ now arise in which the events $\bigwedge_{e_i \in P_j} x_i$ and $\bigwedge_{e_i \in P_s} \bar{x}_i$ are neither disjoint nor independent. Nevertheless, we can expand E so that every term is a *product*, that is, a conjunction of basic variables and their negations, and all products are disjoint. Then logical simplification can remove terms that contain $x_i \bar{x}_i$, for example, and amalgamate two terms of the form $x_i \wedge T$ and $\bar{x}_i \wedge T$ to form the term T . The result is a disjunction (“sum”) of terms, each of which is a conjunction (“product”), and every two of the products are disjoint. This is a *sum-of-disjoint-products* form.

In general, the goal of Boolean methods is to find a “short” Boolean expression for the event of network operation, whose numerical probability of occurrence can be calculated directly. Many different sum-of-disjoint-product forms exist, and effort typically focuses on selecting one that can be both easily produced and easily evaluated.

Inclusion–Exclusion

When $\mathcal{MP} = \{P_1, \dots, P_h\}$ is the set of minpaths, we have seen that the event of network operation is $\bigvee_{P \in \mathcal{MP}} \bigwedge_{e_i \in P} x_i$. Reliability is the probability that this event occurs, that is, $\Pr[\bigvee_{P \in \mathcal{MP}} \bigwedge_{e_i \in P} x_i]$. In words, this simply states that at least one minpath is operating. For a specific minpath P_j , its probability of operation $\Pr[P_j] = \prod_{e_i \in P_j} p_i$.

Consider computing $\sum_{j=1}^h \Pr[P_j]$. Certainly, every event in which a minpath operates is accounted for in this sum. Unfortunately, the event in which P_j and P_ℓ both operate is included twice in the sum. To attempt to correct this, we calculate the probability that both operate, $\Pr[P_j \wedge P_\ell] = \prod_{e_i \in P_j \cup P_\ell} p_i$, and for all distinct choices of j and ℓ subtract this correction from the sum. However, now when three minpaths P_j , P_k , and P_ℓ all operate, the event was included three times in the initial sum (once each for j , k , and ℓ) and then subtracted three times in the correction (once each for $\{j, k\}$, $\{j, \ell\}$, and $\{k, \ell\}$), and a further addition is needed.

Carrying this to its logical conclusion, for a subset S of $\{1, \dots, h\}$, let $\mathcal{MP}_S$ be the set of minpaths indexed by S , let π_S be the set $\cup_{j \in S} P_j$, and compute $\Pr[\pi_S] = \prod_{e_i \in \pi_S} p_i$. Repeatedly applying inclusion/exclusion as above, we obtain $\Pr[\bigvee_{P \in \mathcal{MP}} \bigwedge_{e_i \in P} x_i] = \sum_{S \subseteq \{1, \dots, h\}} (-1)^{|S|+1} \Pr[\pi_S]$. Naturally, it is not desirable to expand this expression out completely, and hence one typically attempts to simplify this expression both logically and arithmetically. One very important feature of inclusion/exclusion methods is that, if we consider only those subsets S that have a fixed maximum size m , we obtain an absolute bound on the reliability. Indeed, when m is odd, we obtain an upper bound, and when m is even we obtain a lower bound. Treating ever larger values of m causes these bounds to converge to the true reliability.

Reliability Polynomials

Whether Boolean methods, inclusion–exclusion, or state-based methods are used, the sets of states, minpaths, or mincuts are typically examined explicitly. As a result, often a further simplifying assumption is made. Suppose that every edge operates with the same probability p . Then, every state in which exactly i edges operate and $m - i$ fail arises with the same probability $p^i(1 - p)^{m-i}$ as every other. This suggests that we may not need to examine each operating state, but instead compute the number N_i of operating states with i edges. If we can count operating states in this way, the reliability is given by $\sum_{i=0}^m N_i p^i (1 - p)^{m-i}$. This is one form of the *reliability polynomial*.

Unless we can compute or bound the coefficients $\{N_i\}$ without essentially listing all operating network states, this is merely a device for simplifying the expression, not one for accelerating its computation. To accomplish the latter, one exploits combinatorial structure. When $\mathcal{P}$ is the set of all pathsets, let $\mathcal{F} = \{e_1, \dots, e_m\} \setminus P : P \in \mathcal{P}$. Then $\mathcal{F}$ contains all complements of pathsets. For a coherent reliability problem, $\mathcal{F}$ is closed under taking subsets; that is, it is a *complex* or *hereditary family of sets*. Now, $F_i = N_{m-i}$ is the number of pathset complements that contain exactly i edges, and hence the reliability is $\sum_{i=0}^m F_i p^{m-i} (1 - p)^i$.

An easy example serves to illustrate the use of combinatorial structure. Intuitively, for a coherent system, when more edges operate, the network is more likely to operate. Indeed, an old theorem of Sperner [19] states that $\frac{F_i}{\binom{m}{i}} \geq \frac{F_{i+1}}{\binom{m}{i+1}}$. Simplifying, we obtain that $F_i \geq \frac{m-i}{i+1} F_{i+1}$ or that $F_{i+1} \leq \frac{i+1}{m-i} F_i$. While these inequalities do not determine the coefficients $(F_0, \dots, F_m)$, they do constrain them significantly.

In this vein, effort has focused on using additional structure of reliability complexes, and on the determination of specific coefficients. For the former, Kruskal [20] and Katona [21] establish the tightest inequality for F_i and F_{i+1} in a general complex. Most reliability problems do not lead to arbitrary complexes, and hence better inequalities have been developed for polyhedral complexes, shellable complexes, and matroidal complexes. Indeed, for all-terminal reliability, $\mathcal{F}$ is a representation of the *cographic matroid* of the graph, which permits the use of a substantial body of knowledge concerning matroids [22].

Effort to determine coefficients has been directed at efficient algorithms, so that upper and lower bounds on reliability measures can be efficiently calculated.

RESTRICTED CLASSES OF NETWORKS

A final important concept is the treatment of reliability problems by restricting the structure of the network itself, rather than by restricting the network operation or

relaxing the requirements on what is to be computed. The prototypical example here is given by the series-parallel networks, those networks that can be reduced to a single edge by deletion of irrelevant edges, contraction of mandatory edges, and series and parallel reductions. These transformations underlie a linear-time algorithm for computing two-terminal reliability, and easy variants of them extend efficient algorithms to k -terminal reliability and k -resilience.

Despite these successes with series-parallel networks, success with other classes arising in practice has been limited. The natural generalization to graphs of bounded treewidth leads to more general, efficient algorithms [23] but in general networks that are planar and/or have bounded maximum degree remain $\#P$ -hard [4]. Nevertheless, approximation and bounding techniques may exploit such additional structure effectively, as for example in the use of Delta-Wye transformations in the estimation of reliability for planar networks [24].

Finally, improved methods for restricted classes of graphs can be used to limit the number of factoring steps in pivotal decomposition, to simplify portions of a Boolean expression or avoid the need for certain terms in an inclusion-exclusion expansion, or to further constrain the values of coefficients in reliability polynomials. Indeed, the application of the many methods outlined here together often provides a more thorough analysis than any of the individual methods provides in isolation.

CONCEPTUAL MODELING FOR SIMULATION

STEWART ROBINSON
Warwick Business School,
University of Warwick,
Coventry, UK

In broad terms, conceptual modeling is the process of abstracting a model from the real world. The modeler is presented with a problem situation that is amenable to simulation modeling, based on which he/she has to determine what aspects of the real world to include, and exclude, from the model, and at what level of detail to model each aspect. These decisions should generally be a joint agreement between the modeler and the problem owners, that is, the stakeholders who require the model to aid decision making.

This article provides an overview of the field of conceptual modeling for simulation. The article starts by describing what is meant by conceptual modeling after which various definitions of the term *conceptual model* are explored. Approaches to developing conceptual models are then discussed, which covers the requirements of a conceptual model, principles of modeling, conceptual modeling frameworks, and methods of model simplification. Finally, ideas for future research in the field of simulation conceptual modeling are provided. Throughout the article the focus is on conceptual modeling for discrete-event simulation [1], although the concepts are also useful to other forms of simulation modeling and modeling more generally.

WHAT IS CONCEPTUAL MODELING?

To understand conceptual modeling it is useful to set it within the wider context of the modeling process for simulation. Figure 1 shows the key artifacts of conceptual modeling [note: an “artifact” is something “made by human workmanship” (Chambers Twentieth

Century Dictionary)]. The “cloud” represents the real world (current or future) within which the problem situation resides; this is the problem that is the basis for the simulation study. The four rectangles represent specific artifacts of the (conceptual) modeling process. These are as follows:

- *System Description*. A description of the problem situation and the system in which the problem situation resides.
- *Conceptual Model*. “The conceptual model is a non-software-specific description of the computer simulation model (that will be, is, or has been developed), describing the objectives, inputs, outputs, content, assumptions, and simplifications of the model.” (2, p. 283).
- *Model Design*. The design of the constructs for the computer model (data, components, model execution, etc.) [3].
- *Computer Model*. A software-specific representation of the conceptual model.

These artifacts are quite separate. This is not to say that they are always explicitly expressed, with the exception of the computer model. For instance, the system description, conceptual model, and model design may not be (fully) documented and can remain within the minds of the modeler and the problem owners. It is, of course, good modeling practice to document each of these artifacts.

The model design and computer model are not strictly part of conceptual modeling, but they do embody the conceptual model within the design and code of the model. These artifacts are included in Fig. 1 for completeness. Our main interest here is in the system description and conceptual model that make up the process of conceptual modeling; as represented by the shape with a dashed outline in Fig. 1. It should also be noted that the system description and conceptual model are independent of any specific software. It is only the model design and computer model

Figure 1. Artifacts of conceptual modeling. [Source: adapted from Kotiadis and Robinson (4, p. 952)].

that are specific to the software chosen for the implementation of the conceptual model.

It is important to recognize the distinction between the system description and the conceptual model. The system description relates to the problem domain, that is, it describes the problem and the real world within which the problem resides. The conceptual model belongs to the model domain in that it describes those parts of the system description that are included in the simulation model and at what level of detail to model. The author's experience is that these two artifacts are often confused and seen as indistinct.

The definitions here are close to those used by Zeigler [5]. He describes five concepts:

- *The Real System.*
- *The Experimental Frame.* The limited set of circumstances under which the real system is observed or experimented with (i.e., specific input–output behaviors).
- *The Base Model.* A model that is capable of accounting for all the input–output behavior of the real system (it cannot be fully known).
- *The Lumped Model.* A simplified model with components lumped together and interactions simplified (it can be fully known and is valid within a chosen experimental frame).

- *The Computer.* The computational device for implementing the lumped model.

Although the correspondence is not exact, the system description in Fig. 1 roughly corresponds to the base model, the difference being that the base model cannot be fully known while the system description embodies all that is known about the real system; it is a subset of the base model. Meanwhile, the conceptual model corresponds to the experimental frame and lumped model together. It is the objectives of the model that define the input–output behaviors (experimental frame) of interest and the content of the model that embodies the simplifications defined by the lumped model; note that objectives and content are central to the definition of a conceptual model. Zeigler is also very clear that the model and the computer (program) are quite distinct. In the same way, Fig. 1 shows that the conceptual model is separate from the model design and computer model.

The arrows in Fig. 1 represent the flow of information; for instance, information about the real-world feeds into the system description. The processes that drive the flow of information are described as knowledge acquisition, model abstraction, design, and coding. The arrows are not specifically representative of the ordering of the steps

within the modeling process, which we know are highly iterative [6,7]. In other words, a modeler may return to any of the four processes at any point in a simulation study, although there is some sense of ordering in that information from one artifact is required to feed the next artifact.

The dashed arrow shows that there is a correspondence between the computer model and the real world. The degree of correspondence depends on the degree to which the model contains assumptions that are correct, the simplifications maintain the accuracy of the model, and the computer code is free of errors. Because the model is developed for a specific purpose, the correspondence with the real world relates only to that specific purpose. In other words, the model is not a general model of the real world, but a simplified representation developed for a specific purpose. The issue of whether the level of correspondence between the model and the real world is sufficient is an issue of verification and validation [6,8–10]. Both conceptual modeling and validation are concerned with developing a simulation of sufficient accuracy for the purpose of the problem being addressed. As a result, there is a strong relationship between the two topics, conceptual modeling being concerned with developing an appropriate model and validation being concerned with whether the model is appropriate.

Knowledge Acquisition and Model Abstraction in Conceptual Modeling

Our attention now turns to concentrate on the specific processes that lead to the development of a conceptual model: knowledge acquisition and model abstraction. The system description is obtained through knowledge acquisition. Knowledge and information about the real world is acquired from subject matter experts (or domain experts) and observations. The conceptual model is obtained through model abstraction. The modeler and problem owners jointly agree on what parts of the system description to model and at what level of detail. We now explore knowledge acquisition and model abstraction in some more detail.

Knowledge Acquisition. Because the real world is not fully known or knowable, the system description is only a partial representation of the real world. There are limits to the knowledge about the real world because of the following points:

- The real world has not been observed in all possible states. If the system exists, it will not have been in every state possible and so cannot have been observed in every state. In many cases, the system does not yet exist; the only state in which it has been observed may be a design drawing.
- Observations about the real world are subject to error. Errors frequently occur in data collected from real systems, particularly where humans are recording the information.
- Observations about the real world are incomplete. Observers will not have been able to record every aspect of the state of the system, and often such information is very limited.
- Observations are subject to observer perceptions. Different observers may interpret events in a system differently. Hence, there may be multiple accounts of the same phenomenon.

Further to this, the nature of the problem situation implies that there are a limited set of modeling objectives. It is desirable to develop a model that addresses only those objectives, rather than a general model of the system. Among other benefits (the section titled “Model Abstraction”), this saves time and reduces data requirements. Hence, the system description (and conceptual model) need focus only on the parts of the real world that are relevant to the problem situation and the modeling objectives.

Because the real world is not fully known or knowable, *assumptions* must be made concerning the real world. “*Assumptions* are made when there are either uncertainties or beliefs about the real world being modelled” (2, p. 283). In general, assumptions are made by the problem owners in consultation with the modeler.

It is good practice to document assumption and assess them for the confidence that can be placed in them and their likely impact on the performance of the real system. Critical assumptions (low confidence, high impact) can be assessed later with the model by performing sensitivity analysis.

Model Abstraction. Model abstraction is important because it is not desirable to model all that is known about the real world, even that which is relevant to the problem situation and modeling objectives. The benefits of simpler models are well documented [11–16]:

- simple models can be developed faster;
- simple models are more flexible;
- simple models require less data;
- simple models run faster;
- the results are easier to interpret since the structure of the model is better understood.

Through abstraction the conceptual model becomes a partial representation of the system description. This is achieved by reducing the scope of the conceptual model from that of the system description and/or by reducing the level of detail in the conceptual model from that of the system description. Both of these imply a process of *simplification*. “*Simplifications* are incorporated in the model to enable more rapid model development and use, and to improve transparency” of the model (2, p. 283). The process of simplification should focus on maintaining sufficient accuracy for addressing the problem situation/modeling objectives.

In general, simplifications are made by the modeler in consultation with the problem owners. It is a good practice to document all simplifications and to assess them for their likely impact on the accuracy of the model. It is unlikely, of course, that high impact simplifications would be appropriate as this implies a model which deliberately embodies significant inaccuracies.

Summary

In understanding conceptual modeling it is important to recognize two distinct elements.

First, within the problem domain is the need to acquire knowledge about the real world and to derive a system description. This process entails making assumptions. Second, within the model domain is the need to abstract a conceptual model from the system description. Within this process, simplifications are made.

As discussed above, the conceptual model may, or may not, be formally expressed and documented. What is certain is that the modeler always carries out the conceptual modeling process in a simulation study; in other words, the modeler makes decisions about the scope and level of detail of the model. Whether this is made explicit (it is documented in some fashion) depends on the level of formality in the modeling process.

A final point is that although we might consider there to theoretically be a right conceptual model for a specific simulation study, it is extremely unlikely that this model could be identified in practice. We might propose that the “right conceptual model” is the model that generates exactly the required level of accuracy with the minimum modeling effort. In practice, we can think only in terms of conceptual models that are better and worse, that is, more or less likely to provide the required level of accuracy with a reasonable amount of effort. The aim of a modeler should be to identify the best conceptual model possible given the constraints of knowledge, data, resource, and time.

DIFFERING OPINIONS ABOUT THE DEFINITION OF A CONCEPTUAL MODEL

Above, the definition for a conceptual model used is “the conceptual model is a non-software-specific description of the computer simulation model (that will be, is, or has been developed), describing the objectives, inputs, outputs, content, assumptions, and simplifications of the model” (2, p. 283). This is by no means an agreed definition. It is hard to find specific definitions for the term *conceptual model* in the simulation and modeling literature, although some authors do discuss the term more generally. Much of this discussion relates to military simulation modeling,

which by nature tends to entail large-scale (and sometimes distributed) models.

Pace defines a conceptual model as “a simulation developer’s way of translating modeling requirements . . . into a detailed design framework . . . , from which the software that will make up the simulation can be built” (17, p. 1). In short, the conceptual model defines what is to be represented and how it is to be represented in the simulation. Pace sees conceptual modeling as being quite narrow in scope, viewing objectives and requirements definition as precursors to the process of conceptual modeling. The conceptual model is largely independent of software design and implementation decisions. Pace [18] identifies the information provided by a conceptual model as consisting of assumptions, algorithms, characteristics, relationships, and data.

Lacy *et al.* [19] further this discussion reporting on a meeting of the Defence Modeling and Simulation Office (DMSO) to try and reach a consensus on the definition of a conceptual model. The paper describes a plethora of views, but concludes by identifying two types of conceptual model: a *domain-oriented* model that provides a detailed representation of the problem domain (similar to the system description in Fig. 1) and a *design-oriented* model that describes in detail the requirements of the model (similar to the conceptual model in Fig. 1). The latter is used to design the model code. Meanwhile, Haddix [20] points out that there is some confusion over whether the conceptual model is an artifact of the user or the designer. This may, to some extent, be clarified by adopting the two definitions of Lacy *et al.* above.

Borah offers the following definition “a simulation conceptual model is an abstraction from either the existing or a notional physical world that serves as a frame of reference for further simulation development by documenting simulation-independent views of important entities and their key actions and interactions. A simulation conceptual model describes what the simulation will represent, the assumptions limiting those representations, and other capabilities needed to satisfy the stakeholder’s requirements.

It bridges between these requirements, and simulation design.” (21, p. 3).

Meanwhile, Balci [22] discusses the role of a conceptual model in model reuse. In this context, he sees a conceptual model as a repository of knowledge about a particular problem domain that can be reused by a community of interest for developing a series of models.

The key areas of agreement in these discussions and definitions are that the conceptual model in some way describes the simulation model and that it is independent of the model code or software.

One specific area where the definition of a conceptual model used in this article differs from others is with the inclusion of the objectives of the model as part of the conceptual model. Others would consider the model objectives to be distinct from the conceptual model. Whereas the author agrees that the task of setting the modeling objectives can be separated from the task of defining the model, the artifacts of modeling objectives and conceptual model are not separate; the conceptual model cannot exist without the objectives of that model. In other words, there is a difference between defining an artifact and the task(s) that lead to the creation of that artifact. Our attention now turns to considering the task of developing a conceptual model.

DEVELOPING CONCEPTUAL MODELS

The process of developing a conceptual model is one of determining the content of the simulation model, what to include in and exclude from a model. This can be split into two components, the scope and level of detail (2, p. 283):

- *The Scope of the Model.* the model boundary or the breadth of the real system that is to be included in the model.
- *The Level of Detail.* the detail to be included for each component in the model’s scope (in effect, the level of abstraction).

The question is how does a simulation modeler decide what the scope and level of

detail of a model should be? This question is not straightforward especially as conceptual modeling is very much more an art than a science. Indeed, Henriksen [23] identifies the need for creativity in the conceptual modeling process. Schmeiser (24, p. 40) points out that “while abstracting a model from the real world is very much an art, with many ways to err as well as to be correct, analysis of the model is more of a science, and therefore easier, both to teach and to do.” The need for creativity does not, however, excuse the need for guidelines on how to model [25]. Ferguson *et al.* (26, p. 24), writing about software development, point out that in “most professions, competent work requires the disciplined use of established practices. It is not a matter of creativity versus discipline, but one of bringing discipline to the work so creativity can happen.”

So what guidance is available to aid the conceptual modeling process? In sum, the guidance can be placed into four categories: requirements of a conceptual model, principles of modeling, conceptual modeling frameworks, and methods of model simplification. Each of these is now discussed in turn.

Requirements of a Conceptual Model

The key requirement is to avoid an overly complex model. As per Occam’s razor, *plurality should not be posited without necessity* (William of Occam; quoted from Ref. 27), the conceptual modeling mantra is one of developing the simplest model possible to meet the objectives of the simulation study. Figure 2 aims to demonstrate the reasons for this. This

Figure 2. Simulation model complexity and accuracy. [Source: Taken from Robinson (2, p. 287).]

shows a sketch based on experience in which increasing levels of complexity (scope and level of detail) lead to diminishing returns in terms of model accuracy. The model will never be 100% accurate, as this is impossible to achieve; all models are simplifications. Eventually, it is argued that increased complexity leads to reduced model accuracy. This is because neither knowledge nor the data are available to support this level of complexity. For instance, it is not possible to model every nuance of human interaction in a service system, during the evacuation of a building, or in combat.

This desire for the simplest model possible is not to negate the need for complex models; instead, it is an appeal to avoid unnecessary complexity. There are situations where a complex model is required.

Developing the theme of the requirements of a conceptual model further, there are some discussions on more specific criteria for a “good” model. These are summarized in Table 1. Robinson [2] suggests that such criteria are useful for guiding modelers, and the problem owners, when thinking about the scope and level of detail for a model.

While exhortations to develop the simplest model possible and requirements of conceptual models might be useful, neither provides specific guidance on how to determine the conceptual model for a specific simulation study. Modeling principles and framework, and methods of simplification, go at least some way to helping in this respect.

Principles of Modeling

Providing a set of guiding principles for modeling is one approach to advising simulation modelers on how to develop (conceptual) models. For instance, Pidd [34] describes six principles of modeling:

- model simple, think complicated;
- be parsimonious, start small and add;
- divide and conquer, avoid megamodels;
- use metaphors, analogies, and similarities;
- do not fall in love with data;
- modeling may feel like muddling through.

Table 1. Requirements of a Conceptual Model

Pritsker [28]	Henriksen [29]	Nance [30]	Willemain [31]	Brooks and Tobias [32]	van der Zee and van der Vorst [33]	Robinson [2]
Valid	Fidelity	Model	Validity	Model describes behavior	Completeness	Validity
Understandable	Execution speed	correctness	Aptness for	of interest	Transparency	Credibility
Extendible	Ease of	Testability	client's problem	Accuracy of the model's		Utility
Timely	modification	Adaptability	Value to client	results		Feasibility
	Elegance	Reusability	Usability	Probability of containing		
		Maintainability	Feasibility	errors		
				Validity		
				Strength of theoretical		
				basis of model		
				Ease of understanding		
				Portability and ease with		
				which model can be		
				combined with others		
				Time and cost to build		
				model		
				Time and cost to run		
				model		
				Time and cost to analyze		
				results		
				Hardware requirements		

The central theme is one of aiming for simple models through evolutionary development. Others have produced similar sets of principles (or guidelines); for instance, Morris [35], Musselman [36], Powell [37], Pritsker [38], and Law [1].

These principles provide some useful guidance for those developing conceptual models. It is useful to encourage modelers to start with small models and to gradually add scope and detail. What such principles do not do, however, is to guide a modeler through the conceptual modeling process. When should more detail be added? When should elaboration stop? There is a difference between giving some general principles and guiding someone through a process.

Conceptual Modeling Frameworks

A modeling framework goes beyond the idea of guiding principles by providing a specific set of steps that guide a modeler through the development of a conceptual model. There have been some attempts to provide such frameworks going back to Shannon [39] who describes four steps: specification of the model's purpose; specification of the model's components; specification of the parameters and variables associated with the components; and specification of the relationships between the components, parameters, and variables.

Both Nance and Pace have devised frameworks that relate primarily to the development of large-scale models in the military domain. Nance [30] outlines the conical methodology. This is an object-oriented, hierarchical specification language that develops the model definition (scope) top-down and the model specification (level of detail) bottom-up. A series of modeling steps are outlined. Balci and Nance [40] focus specifically on a procedure for problem formulation. Meanwhile, Arthur and Nance [41] identify the potential to adopt software requirements engineering (SRE) approaches for simulation model development. They also note that there is little evidence of SRE actually being adopted by simulation modelers, which is surprising given the close correspondence between the two fields. (The author contends that the key difference between SRE and

simulation conceptual modeling is the need for abstraction in simulation.)

Pace [17,18] explores a four-stage approach to conceptual model development, similar to that of Shannon: collect authoritative information on the problem domain; identify entities and processes that need to be represented; identify simulation elements; and identify relationships between the simulation elements. He also identifies six criteria for determining which elements to include in the conceptual model. These criteria focus on the correspondence between real-world items and simulation objects [18].

Outside of the military domain there is quite limited work on conceptual modeling frameworks. Brooks and Tobias [42] briefly propose a framework for conceptual modeling, but go no further in expanding upon the idea. Papers by Guru and Savory [43] and van der Zee and van der Vorst [33] propose conceptual modeling frameworks in some more detail. Guru and Savory propose a set of modeling templates (tables) useful for modeling physical security systems. Meanwhile, van der Zee and van der Vorst propose a framework for supply chain simulation. Both are aimed at an object-oriented implementation of the computer-based simulation model. Meanwhile, Kotiadis [44] looks to the ideas of soft operational research, and specifically soft systems methodology (SSM) [45], for aiding the conceptual modeling process. She uses SSM to help understand a complex health-care system and then derives the simulation conceptual model from the SSM "purposeful activity model."

Robinson [46] proposes a conceptual modeling framework that guides a modeler from identification of the modeling objectives through to determining the scope and level of detail of a model. Birta and Arbez [47] have devised the ABCmod conceptual modeling framework. This provides a detailed procedure for identifying the components and relationships for a discrete-event simulation model.

Such frameworks certainly appear to have potential for aiding the development of conceptual models, but they cannot be said to be fully developed or in common use. One interesting issue is whether frameworks are

best aimed at a specific domain (e.g., supply chain) or whether generic frameworks can be devised.

Methods of Model Simplification

Simplification entails removing scope and detail from a model or representing components more simply while maintaining a sufficient level of accuracy. In Zeigler's [5] terms this could be described as further lumping of the lumped model. In many respects this is the opposite of the start small and add principle of Pidd [27].

There are quite a number of discussions on simplification, both in the simulation and the wider modeling context. Morris [35] identifies some methods for simplifying models: making variables into constants, eliminating variables, using linear relations,

strengthening the assumptions and restrictions, and reducing randomness. Ward [12] provides a similar list of ideas for simplification. Meanwhile, Courtois [48] identifies criteria for the successful decomposition of models in engineering and science.

For simulation modeling, Zeigler [5] suggests four methods of simplification: dropping unimportant components of the model, using random variables to depict parts of the model, coarsening the range of variables in the model, and grouping components of the model. Yin and Zhou [49] build upon Zeigler's ideas, discussing six simplification techniques and presenting a case study.

Innis and Rexstad [11] enter into a detailed discussion about how an existing model might be simplified. They provide a list of 17 such methods, although they do not claim that these are exhaustive. Robinson

Table 2. Research Themes for Conceptual Modeling^a

The Problem/Modeling Objectives Domain	The Model Domain
Use of 'Soft OR' as a basis for determining a simulation conceptual model	Identifying dimensions for determining the performance of a conceptual model
How best to work with subject matter experts in forming a conceptual model	Comparing different models in the same problem domain
How to organize and structure the knowledge gained during conceptual modeling	Studying expert modelers to understand how they form conceptual models
Alternative sources of contextual data/information for conceptual modeling, including paper, interview, and electronic sources	How software engineering techniques might aid simulation conceptual modeling
Developing curricula to include conceptual modeling in university and industry courses on simulation	Adopting/developing appropriate model representation methods
	Exploring methods of model simplification
	Identifying, adapting, and developing conceptual modeling frameworks
	Refining models through agreement between the modeler and stakeholders—"convergent design"
	Exploring the creative aspects of modeling
	Understanding the organizational diffusion and acceptance of models
	Investigating the impact of other modeling tasks on the conceptual model (iteration in the simulation life cycle)
	Understanding the effect of throw away models versus models with longevity—for example, the time spent on conceptual modeling, documentation, and organizational diffusion

^aSource: Taken from Robinson (51, p. 151).

[50] also lists some methods for simplifying simulation models.

Such ideas are useful for simplifying an existing (conceptual) model, but they do not guide the modeler over how to bring a model into existence. Model simplification acts primarily as a redesign tool and not a design tool.

FUTURE RESEARCH IN CONCEPTUAL MODELING

Work on conceptual modeling has been sporadic over the past 40 or more years. At present there are a number of groups with a specific interest in the topic, for instance, the NATO Research and Technology Organisation Activity on Conceptual Modelling for Modelling and Simulation (www.rta.nato.int/Activities.aspx#), the stream of papers at the Simulation Interoperability Workshops (www.sisostds.org), and the conceptual modelling group formed around the UK Simulation Workshops (conceptualmodeling.info). Indeed, conceptual modeling is currently seen as an important topic in developing the field of simulation.

At a meeting in 2006, the latter group identified a set of key research themes for conceptual modeling. These are reported in Robinson [51] and summarized in Table 2. The themes were split between those belonging to the problem domain and the model domain (Fig. 1). Such a list may prove useful for those considering research in this area.

CONCLUSION

This article provides an overview of the field of simulation conceptual modeling. It explores the meaning and process of conceptual modeling, and provides some ideas on areas for future research. Conceptual modeling is certainly a field that is ripe for further research and a field that is much in need of further development. It is also a field that is difficult to work in because conceptual modeling, by nature, is more of an art than a science.

CONDITION-BASED MAINTENANCE UNDER MARKOVIAN DETERIORATION

BORA ÇEKYAY

SÜLEYMAN ÖZEKICI

Department of Industrial Engineering,
Koç University, Istanbul, Turkey

INTRODUCTION

Maintenance actions are vital for companies to increase reliability and availability of the production system and to decrease production costs. At the same time, Bevilacqua and Braglia [1] state that maintenance may require extensive expenditure, which may vary from 15 to 70% of the total production cost depending on the industry. For instance, the total amount of money spent for maintenance is more than \$200 billion in the United States every year as observed by Chu *et al.* [2]. Moreover, a significant portion of total work force in a company is employed in maintenance departments; Waeyenbergh and Pintelon [3] estimate that this is up to 30% or more in chemical process industries. These observations indicate that optimizing the obvious trade-off between maintenance costs and productivity will have a very significant impact on the total cost. This is why it is not surprising that an extensive body of literature on optimal maintenance has accumulated in the last 50 years. The review papers [4–13] survey hundreds of papers in chronological order on optimal maintenance problems.

In general, there are two types of maintenance considered in the literature: corrective maintenance (CM) and preventive maintenance (PM). CM involves actions performed after a failure to restore the system to a better condition. Sim and Endrenyi [14] define PM as the actions performed regularly at preselected times (not necessarily identical) to reduce or eliminate the accumulated

deterioration. PM can be further classified into two main classes: time-based preventive maintenance (TBPM) and condition-based maintenance (CBM). System lifetime is considered as a random variable in TBPM and its distribution is determined by statistical analysis. Then, optimal PM actions are planned according to a mathematical model developed using the failure distribution of the system and related maintenance costs. On the other hand, Wang *et al.* [15] state that maintenance decisions are made according to the actual state or condition of the system under CBM policies. The state of the system may take either discrete values such as real or intrinsic age (e.g., number of flights for planes) or predefined deterioration levels, or continuous values such as temperature, vibration, cumulative wear, and so on. In the former one, multistate Markov decision processes are generally used to determine the states at which a preventive replacement decision is optimal to minimize a cost criteria. In the latter one, the system is generally subject to continuous wear or deterioration. The general purpose of the models developed to investigate such systems is to find an optimal threshold above which a preventive replacement decision is optimal. In this article, we focus on CBM models under Markovian deterioration, where the state of the system can be classified into one of a finite number of states. For more information on CBM models with continuous deterioration, we refer the interested reader to Refs 2 and 15–25 and the references cited in these papers.

CBM models are further classified by the time points at which the state of the system is observed by the decision maker. There are three types of inspection policies applied in CBM literature: continuous inspection policy (CIP), periodic inspection policy (PIP), and sequential inspection policy (SIP). Systems are always monitored or the state of the system is always known by the decision maker under CIP. On the other hand, the condition of the system under PIP or SIP is known only at some discrete time points. The main

difference between PIP and SIP is that in PIP, the system is inspected and its state is observed at equal time intervals, but these intervals do not have to be equal in SIP. If we apply PIP or SIP, the time points at which the system will be inspected must be determined carefully since more frequent inspections will increase the related inspection cost and less frequent inspections will decrease the ability to maintain the survival of the system. We will also review some important optimal inspection and replacement models for which a control-limit policy is optimal.

Although they may not be optimal even under very intuitive conditions (as we will illustrate by an example later), control-limit policies are studied extensively in the literature. The significance of control-limit policies is that they are very easy to understand and implement. Similarly, there are many CBM policies defined using several thresholds in the literature. These models are important because they are also easy to apply and they can reasonably describe the deterioration-maintenance process of some systems in real-world applications. We will also review some of the important papers that analyze maintenance policies defined via several thresholds.

In this article, we review papers where the state of the system at any time can be determined perfectly by observations. However, in recent years, there is growing interest in partially observed systems where the actual state of the system is unknown and can be estimated (imperfectly) based on observed conditions. Partially observed Markov decision processes are generally used to analyze such models. We refer the interested reader to Ghasemi *et al.* [26] and Maillart [27] for recent advances in this research area. Moreover, parameter estimation of the partially observed models is also important to apply these models to real-life situations by utilizing on-line information about the state of the system. Lin and Makis [28] propose a recursive maximum likelihood algorithm which is applicable to systems that deteriorate according to a Markov process.

In the second section, the general assumptions and notation used in CBM models with Markovian deterioration are given. The third and fourth sections are on

optimal replacement, and optimal inspection/replacement models, respectively where optimality of control-limit policies is established. We conclude the article with fifth section, by summarizing some other important maintenance models where policies are described by a few thresholds.

GENERAL ASSUMPTIONS

We shall concentrate specifically on optimal policies for CBM models with Markovian deterioration. In the most generic sense, these models satisfy the following main assumptions.

1. The system can be observed to be in one of the $M + 1$ states from the set $F = \{0, 1, \dots, M - 1, M\}$, where state 0 represents a brand-new system, states $1, 2, \dots, M - 1$ represent intermediate deterioration levels in ascending order, and M denotes system failure.
2. Transitions among the deterioration levels at successive decision times follow an increasing Markov chain with an upper-triangular transition probability matrix $P = [P_{ab}]$, where P_{ab} is the probability that the next deterioration level of the system will be b given that current level is a for every $a, b \in F$.
3. Holding time in each level is a random variable with parameters which may or may not depend on the deterioration level. Let t_a be the holding time in state $a \in F$ with mean $\bar{t}_a$. We suppose that t_a is exponentially distributed for every a so that the deterioration process is a Markov process. Otherwise, it is a semi-Markov process.
4. Replacement durations may be negligible or random. Let r_a denote the replacement duration with mean $\bar{r}_a$ if the replacement decision is given when the system is in state $a \in F$. There is always a replacement cost c_a if the system is replaced when its deterioration level is $a \in F$.
5. The system may be inspected continuously, periodically, or sequentially.

6. A state occupancy cost h_a may be incurred when the system is occupying level $a \in F$. When the system fails, a failure cost K is incurred.
7. At each decision epoch, there are two alternative decisions: the system will be replaced ($s_a = 1$) or not replaced ($s_a = 0$), respectively if the system is in state $a \in F$ at that decision epoch. The replacement action is assumed to be perfect so that the system state is restored to 0 after the replacement.
8. The objective of the problem is to minimize the expected total discounted cost or the average cost per time.

These types of maintenance problems have been studied in the literature since the 1960s. In general, there are two types of research papers where the first type defines a mathematical model of the maintenance problem and obtains a policy (usually a control-limit policy), which solves the problem optimally. The second type investigates the problems using a given simplified policy that is not necessarily optimal and finds the optimum parameters of this class of policies that minimize a cost function. In the following two sections, we will review papers of the first type for replacement and inspection/replacement models respectively. The final section focuses on papers of the second type.

OPTIMAL REPLACEMENT MODELS

One of the earliest and basic cases where the deterioration process is described by a Markov chain is analyzed by Derman [29]. It is assumed that the system is inspected at equally spaced points in time and the system is classified into one of the deterioration levels after each inspection. The holding times are not considered and the decision model is formulated based on the deterioration levels of the system observed at each inspection time. It is assumed that the successive levels follow a Markov chain whose transition matrix is monotone so that the cumulative matrix

$$\bar{P}_{ab} = \sum_{k=b}^M P_{ak} \quad (1)$$

is nondecreasing in a for every $b \in F$. The other assumptions of this model are that the replacement duration is equal to one inspection interval, replacement costs do not depend on the deterioration level ($c_a = c$ for every a and some c), and there is no state occupancy cost ($h_a = 0$). The dynamic programming equation is

$$v(a) = \begin{cases} c + K + \alpha \sum_{b=0}^M P_{0b} v(b), & \text{if } a = M, \\ \min \left\{ \alpha \sum_{b=0}^M P_{ab} v(b), c + \alpha \sum_{b=0}^M P_{0b} v(b) \right\}, & \text{if } a \neq M, \end{cases} \quad (2)$$

where $0 \leq \alpha < 1$ is the periodic discount factor and $v(a)$ is the total expected discounted cost. In our discussions, we will present details primarily on $v(a)$ with the understanding that the average cost can be obtained in a similar fashion. It is proven that the optimal policy has a control-limit structure. In particular, there exists $a^* \in F$ such that

$$s_a^* = \begin{cases} 1, & \text{if } a \geq a^*, \\ 0, & \text{if } a < a^*, \end{cases} \quad (3)$$

for every $a \in F$ where s^* denotes the optimal policy. The same model with state occupancy costs incurred each time that the system is inspected is analyzed by Kolesar [30]. The dynamic programming equation now becomes

$$v(a) = \begin{cases} c + h_M + \alpha \sum_{b=0}^M P_{0b} v(b), & \text{if } a = M, \\ \min \left\{ h_a + \alpha \sum_{b=0}^M P_{ab} v(b), c + h_a + \alpha \sum_{b=0}^M P_{0b} v(b) \right\}, & \text{if } a \neq M, \end{cases} \quad (4)$$

and the optimal policies minimizing both total expected discounted cost and average cost are of the control-limit type if h_a and $\bar{P}_{ab}$ are nondecreasing in a .

Kawai *et al.* [31] consider another model where state occupancy costs are not paid during replacement, and all costs are state dependent. The dynamic programming equation is

$$v(a) = \min \left\{ h_a + \alpha \sum_{b=0}^M P_{ab} v(b), c_a + \alpha v(0) \right\}, \quad (5)$$

and it is shown that the optimal policy still has a control-limit structure even when c_a is increasing in a provided that $h_a, h_a - c_a$, and $\bar{P}_{ab}$ are increasing in a .

A generalization of the model in Kolesar [30] is analyzed by Wood [32] by considering the case where the replacement action may fail with a probability $1 - p$ and the occupancy costs are not paid during replacement. The standard recursion for this model can be formulated as

$$v(a) = \begin{cases} c + K + \alpha p v_\alpha(0) + \alpha(1 - p) v_\alpha(M), & \text{if } a = M, \\ \min \left\{ h_a + \alpha \sum_{b=0}^M P_{ab} v_\alpha(b), c + \alpha p v_\alpha(0) + \alpha(1 - p) v_\alpha(a) \right\}, & \text{if } a \neq M. \end{cases} \quad (6)$$

For this model, the optimality of a control-limit policy minimizing the total expected discounted cost and the average cost is proven under the same assumptions used by Kolesar [30]. The model where the occupancy costs are paid during replacement has the dynamic programming equation

$$v(a) = \begin{cases} c + K + h_M + \alpha p v(0) + \alpha(1 - p) v(M), & \text{if } a = M, \\ \min \left\{ h_a + \alpha \sum_{b=0}^M P_{ab} v(b), c + h_a + \alpha p v(0) + \alpha(1 - p) v(a) \right\}, & \text{if } a \neq M. \end{cases} \quad (7)$$

It is shown that the control-limit rule may not be optimal for this case by a counterexample. In the same paper, a constantly monitored system is also investigated with

the assumptions that the replacement duration and holding times are exponentially distributed, and replacement decisions are allowed only when a transition occurs in the deterioration process of the system. It is assumed that the holding times depend on the deterioration level with rate λ_a for level a , but the replacement duration does not with a constant rate λ . The analysis is done by applying uniformization techniques by which a continuous-time Markov decision process can be converted into an equivalent discrete-time Markov decision process. Wood [32] concludes that the optimal policy is control-limit type for both total expected discounted cost and average cost criteria provided that h_a and $\sum_{k=b}^M P_{ak} \lambda_k$ are nondecreasing in a , and occupancy costs are not paid during replacement. It is also proven that the same result holds for the case where the occupancy costs are also paid during replacement if the replacement duration is stochastically smaller than the holding time in each state ($\lambda \geq \lambda_a$). Özekici and Günlük [33] propose some sufficient conditions, which make the lifetime of a system with Markovian deterioration increasing failure rate on average (IFRA), and also show that these conditions imply the optimality of a control-limit policy if the replacement cost does not depend on the deterioration level of the system.

An interesting extension of these models is obtained when failure parameters are modulated by a Markovian mission process. Many missions performed by a device are composed of different stages or phases. Since each phase has different properties, the system may deteriorate in a phase more than it does during another phase. For instance, if you consider a flight of a plane as a mission, you can divide this mission into three basic phases: take-off, cruise, and landing. It is well-known that the degradation of a plane during take-off and landing is much more than it is during cruise. These type of examples stimulate the models where the failure parameters of the system are dependent on a mission process. They are often called *phased-mission systems* or *mission-based systems* in the literature. The optimal maintenance problem of such a system inspected constantly is analyzed by Çekyay

and Özekici [34]. The mission process is a Markov process on some finite state space E with a transition rate vector μ and transition probability matrix Q . Suppose that the deterioration process of the system follows a Markov process with transition rate vector λ_i and upper-triangular transition probability matrix P_i during phase $i \in E$. Let c_i and K_i be the replacement cost and failure cost, respectively during phase i . Note that the replacement cost does not depend on the deterioration level. It is further assumed that if the system fails during a phase, it will perform the same phase after the replacement since it is not yet completed. A state occupancy cost $h_i(a)$ is incurred during phase i if the deterioration level of the system is a . Replacements are instantaneous, a replacement decision can be given only when a change occurs in the mission process or in the deterioration level, and the state occupancy costs are not paid during replacement. Let $v(i, a)$ be the optimal expected total discounted cost if the initial phase is i and the initial deterioration level of the system is a for every $i \in E$ and $a \in F$. The dynamic programming equation is

$$v(i, a) = \min_{s \in A_a} \{r_s(i, a) + \Gamma_s v(i, a)\}, \quad (8)$$

where $A_0 = \{0\}$, $A_M = \{1\}$, $r_1(i, M) = K_i + h_i(0)$, $A_a = \{0, 1\}$ for $a = 1, 2, \dots, M-1$, $r_0(i, a) = h_i(a)$, $r_1(i, a) = h_i(0) + c_i$,

$$\begin{aligned} \Gamma_0 v(i, a) &= \frac{\mu(i) + \lambda_i(a)}{\mu(i) + \lambda_i(a) + \alpha} \\ &\times \left[\frac{\mu(i)}{\mu(i) + \lambda_i(a)} \sum_{j \in E} Q(i, j) v(j, a) \right. \\ &\left. + \frac{\lambda_i(a)}{\mu(i) + \lambda_i(a)} \sum_{b=0}^M P_i(a, b) v(i, b) \right], \end{aligned} \quad (9)$$

for $a = 0, 1, \dots, M-1$, and

$$\Gamma_1 v(i, a) = \frac{\mu(i) + \lambda_i(0)}{\mu(i) + \lambda_i(0) + \alpha}$$

$$\begin{aligned} &\times \left[\frac{\mu(i)}{\mu(i) + \lambda_i(0)} \sum_{j \in E} Q(i, j) v(j, 0) \right. \\ &\left. + \frac{\lambda_i(0)}{\mu(i) + \lambda_i(0)} \sum_{b=0}^M P_i(0, b) v(i, b) \right], \end{aligned} \quad (10)$$

for $a = 1, \dots, M$. The following characterization is obtained using uniformization techniques.

Theorem 1. *Suppose that s^* is the optimal replacement policy. Then, there exists a_i^* for every $i \in E$ such that*

$$s^*(i, a) = \begin{cases} 1, & \text{if } a \geq a_i^*, \\ 0, & \text{if } a < a_i^*, \end{cases}$$

provided that

- (a) P_i is a monotone matrix for every i ,
- (b) $\lambda_i(a)$ is nondecreasing in a for every i ,
- (c) $c_i \leq K_i$ for every i ,
- (d) $h_i(a)$ is nondecreasing in a for every i ,
- (e) there exists a constant c such that $\sup_{i \in E, a \in F \setminus \{M\}} \{\mu(i) + \lambda_i(a)\} \leq c$.

Theorem 1 indicates that the optimal policy has a control-limit structure where the control limits depend on the phases of the mission. The preventive replacement cost c_i is independent of the deterioration level of the system. In real-life applications, this cost may be increasing in the deterioration level since the salvage value of the system decreases as the system deteriorates. Let $c_i(a)$ be the preventive replacement cost of the system with deterioration level a during phase i . Note that the optimal policy can now be obtained by solving Equations (8)–(10) where $r_1(i, a) = h_i(0) + c_i(a)$ for all $a = 0, 1, \dots, M-1$. Suppose further that $c_i(a)$ is increasing in a for every phase as expected. It is clear that this modification is very reasonable and our intuition may indicate that $v(i, a)$ will be increasing in a and the optimal policy will be of the control-limit type. However, the following counterexample shows that the optimal policy may not have a control-limit structure even when $v(i, a)$ is increasing in a .

Example 1. Suppose that $M = 6$ and the system performs a mission with three phases. The transition probability matrix and the transition rates of the mission process are

$$Q = \begin{bmatrix} 0 & 0.4 & 0.6 \\ 0.3 & 0 & 0.7 \\ 0.5 & 0.5 & 0 \end{bmatrix} \quad (11)$$

and

$$\mu = [5 \quad 8 \quad 4]. \quad (12)$$

The transition probability matrices of the deterioration process are

$$P_1 = \begin{bmatrix} 0 & 0.1 & 0.2 & 0.2 & 0.3 & 0.1 & 0.1 \\ 0 & 0 & 0.1 & 0.15 & 0.2 & 0.25 & 0.3 \\ 0 & 0 & 0 & 0.2 & 0.23 & 0.22 & 0.35 \\ 0 & 0 & 0 & 0 & 0.3 & 0.3 & 0.4 \\ 0 & 0 & 0 & 0 & 0 & 0.5 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

$$P_2 = \begin{bmatrix} 0 & 0.1 & 0.2 & 0.2 & 0.2 & 0.1 & 0.2 \\ 0 & 0 & 0.05 & 0.13 & 0.22 & 0.25 & 0.35 \\ 0 & 0 & 0 & 0.17 & 0.22 & 0.23 & 0.38 \\ 0 & 0 & 0 & 0 & 0.24 & 0.32 & 0.44 \\ 0 & 0 & 0 & 0 & 0 & 0.4 & 0.6 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (13)$$

$$P_3 = \begin{bmatrix} 0 & 0.1 & 0.1 & 0.1 & 0.15 & 0.2 & 0.35 \\ 0 & 0 & 0.05 & 0.08 & 0.22 & 0.25 & 0.4 \\ 0 & 0 & 0 & 0.05 & 0.24 & 0.26 & 0.45 \\ 0 & 0 & 0 & 0 & 0.18 & 0.32 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 0.45 & 0.55 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (14)$$

$$v^* = \begin{bmatrix} 312.123 & 337.123 & 352.123 & 372.123 & 526.516 & 562.123 & 587.123 \\ 321.461 & 351.461 & 366.461 & 401.461 & 456.461 & 501.461 & 571.461 \\ 314.990 & 357.354 & 400.434 & 444.990 & 449.990 & 454.990 & 724.990 \end{bmatrix},$$

where the rows and the columns represent the phases and the deterioration levels respectively. It is clear that for phase 1, even when the cost function is increasing, the optimal policy is not the control-limit type.

In all of the papers discussed so far, the holding times are either negligible or

and the related transition rates are

$$\begin{aligned} \lambda_1 &= [1 \quad 2 \quad 3 \quad 3.1 \quad 10 \quad 50] \\ \lambda_2 &= [2 \quad 3 \quad 5 \quad 80 \quad 100 \quad 120] \\ \lambda_3 &= [1 \quad 1.5 \quad 2.5 \quad 40 \quad 45 \quad 50]. \end{aligned}$$

We show that if c depends on the deterioration level of the system, then the optimal policy does not have to be control-limit. Suppose that

$$c = \begin{bmatrix} 15 & 25 & 40 & 60 & 250 & 250 \\ 15 & 30 & 45 & 80 & 135 & 180 \\ 15 & 50 & 95 & 130 & 135 & 140 \end{bmatrix}$$

and

$$h = \begin{bmatrix} 10 & 12 & 14 & 16 & 18 & 20 \\ 5 & 8 & 10 & 12 & 14 & 16 \\ 2 & 3 & 4 & 5 & 6 & 6 \end{bmatrix},$$

where the rows and the columns represent the phases and the deterioration levels respectively, and

$$K = [275 \quad 250 \quad 410],$$

where the columns represent the phases and $\alpha = 0.75$. Then, the optimal replacement policy and optimal costs are

$$s^* = \begin{bmatrix} 0 & 1 & 1 & 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

and

exponentially distributed. However, the optimality of a control-limit policy may be obtained for the models with different (even more general) holding time distributions satisfying some monotonicity properties. A model where replacement and holding times are discrete random variables and the system is monitored continuously is analyzed

by Kao [35]. It is assumed that a replacement decision can only be given after a transition of the deterioration level of the system. The author proves that the optimal policy which minimizes the total discounted expected cost has control-limit structure provided that h_a is nondecreasing in a , $\bar{t}_a$ is nonincreasing in a , P is monotone, and the cost and time for replacement are independent of the deterioration level. In this model, the deterioration process is actually a semi-Markov process where sojourn times are discrete random variables. Following this line of research, So [36] used semi-Markov decision processes to analyze the model where the replacement duration has a general distribution, which is independent of the deterioration level ($\bar{r}_a = \bar{r}$); the holding times are independent and identically distributed random variables, where $\bar{t}_a$ is nonincreasing in a ; h_a and c_a are nondecreasing in a ; and $\sum_{b=a}^M P_{ab}c_b - c_a$ is nondecreasing in a for $1 \leq a < M$. The last assumption might be strict, but it is shown that this condition can be easily verified in some important special cases. It is also assumed that a fixed charge β is incurred, when the system is occupying level 0, to do parametric analysis on β . The optimality of a control-limit policy minimizing average cost is proven under some monotonicity assumptions for every β , in particular, for $\beta = 0$. The author also extends this result to the case where replacement durations are dependent on the deterioration level under the assumptions that $\sum_{b=a}^M P_{ab}c_b - c_a$ is nondecreasing in a for $1 \leq a < M$, $\bar{r}_a$ is nondecreasing in a , $h_a\bar{t}_a$ is nondecreasing in a , and $\sum_{b=a}^M P_{ab}\bar{r}_b - \bar{r}_a + \bar{t}_a$ is nonincreasing in a .

Another study using a semi-Markov process with continuous sojourn times to model the deterioration process of a system is presented by Lam and Yeh [37]. In this model, the holding time in level a has a general distribution F_a with hazard rate function f_a ; state occupancy costs, replacement costs and times are state dependent, and from level a , the deterioration process will make a direct transition either to level $a + 1$ with probability p_a or level M with probability $1 - p_a$. It is assumed that the system is monitored continuously and a decision is given when the system enters a new deterioration level.

When the system enters level a , the decision maker takes a decision to replace the system t_a units of time later if it remains in level a . If $t_a = 0$, then the system is replaced as soon as it enters level a and if $t_a = +\infty$, then the system will not be replaced as long as it stays in level a . The model has the following monotonicity assumptions.

1. The state occupancy cost rate, the replacement cost rate, the expected replacement time, the marginal replacement cost, and the marginal replacement time increase as the system deteriorates,
2. F_a is an increasing failure rate distribution for every a and $f_a(t)$ increases in a for every t , and
3. p_a is nondecreasing in a .

Under these conditions, there exist h^* and k^* with $0 \leq h^* \leq k^* \leq M$, such that

$$t_a^* = \begin{cases} +\infty, & \text{if } a < h^*, \\ s_a, & \text{if } h^* \leq a < k^*, \\ 0, & \text{if } k^* \leq a \leq M, \end{cases}$$

where t_a^* is the optimal decision in level a , and $0 < s_{h^*} \leq s_{h^*+1} \leq \dots \leq s_{k^*-1} < +\infty$. In other words, the system is replaced immediately as soon as it enters one of the states $\{k^*, k^* + 1, \dots, M\}$, and it is never replaced in states $\{0, 1, \dots, h^* - 1\}$. However, in any state $a \in \{h^*, h^* + 1, \dots, k^*\}$, it is replaced after s_a units of time in that state.

In recent years, advances in sophisticated sensor technology has made it possible to continuously observe the real-time condition of a system. This creates an opportunity to design more accurate and timely maintenance policies. The first challenge in using this technology is to find a measure that represents the state of the system based on several data obtained by several sensors built in the system. Chen *et al.* [38] proposed a health index to represent the condition of a system that deteriorates according to a nonstationary Markov chain. They analyze optimal maintenance times that minimize the expected cost per unit time and expected downtime per unit time.

OPTIMAL INSPECTION/REPLACEMENT MODELS

Another interesting research problem involves optimal inspection and replacement where the state of the system can only be observed via inspections performed at selected times. A fixed cost is incurred whenever the system is inspected and then, either a replacement occurs or the time until the next inspection is determined. Such a problem with negligible replacement and inspection times is analyzed by Ohnishi *et al.* [39] who consider a system with Markovian deterioration. It is assumed that holding times are state-dependent exponential random variables; state occupancy and replacement costs are dependent on the deterioration level and a direct transition can occur only to state $a + 1$ or state M . Under some monotonicity assumptions on costs and transition rates, it is shown that the optimal policy minimizing the average cost has a control-limit structure and the optimal time interval between successive inspections becomes shorter as the deterioration level of the system increases. Similar results are obtained by Lam and Yeh [40] for an identical model where replacement and inspection times are not negligible. It is clear that in real-world applications, numerical procedures are necessary to find optimal policies even if it has a control-limit structure. Iterative algorithms are derived for the optimal inspection and replacement problem under different maintenance strategies by Lam and Yeh [40]. These maintenance strategies include failure replacement, age replacement, sequential inspection, periodic inspection, and continuous inspection. These algorithms are valid for a model where the deterioration process is a continuous-time Markov process and from state a , a direct transition can occur only to state $a + 1$ or state M . Numerical procedures for a more general model are proposed by Yeh [41]. In this model, the deterioration process is a semi-Markov process where the holding time in each level follows a general distribution that depends on the level and from level a , direct transitions to levels $a + 1, a + 2, \dots, M - 1, M$ are allowed. Iterative algorithms minimizing the average

cost rate are provided to derive the optimal state-dependent and state-age-dependent inspection/replacement policies. In a state-age-dependent policy, once the state of the system is identified, the maintenance decision is made according to the deterioration level of the system and the time spent in the current state. However, if we apply the state-dependent policy, each maintenance action is determined only according to the deterioration level of the system no matter how long the system has been in that state.

Maillart and Zheltova [42] analyze a system, whose state can only be identified by inspection, using partially observed Markov decision processes. At each decision epoch, the decision maker has three options: replacement, inspection, and do nothing. If the system experiences inspection, the actual state of the system (information level) can be determined perfectly. If the system is not inspected, then the decision will be based on the information available in the previous decision epoch. The authors show the existence of a control-limit rule for this model under some monotonicity assumptions. The optimal decision is to replace the system if the available information level at a decision epoch is over a threshold that depends on the information level.

OPTIMAL MAINTENANCE USING THRESHOLDS

Besides the papers, which investigate the optimality of control-limit policies, there is also abundant literature that focus on a given special class of policies where maintenance decisions are made within that class. This type of model can be useful, especially, when a special policy reasonably describes the deterioration-maintenance process of the system. For instance, an optimal PM model suitable for (not limited to) especially coal pulverizers, circuit breakers, and transformers is proposed by Sim and Endrenyi [14]. In this model, the system is subject to two types of failure: Poisson failures and deterioration failures. The deterioration process is an increasing Markov process where the holding times are exponentially

distributed with a constant rate and $P_{ij} = 1$ for $j = i + 1$. The times to Poisson failures are exponentially distributed with a constant rate independent of the deterioration level of the system. The system is removed from operation periodically for preventive minimal maintenance, which restores the deterioration level to the previous level (i.e., from level i to level $i - 1$ if the deterioration level is i when the PM starts). The duration between two successive minimal PM actions has an Erlang- r distribution with mean $1/\lambda_m$. If a failure occurs, the system is restored to level 0 and the time to repair depends on the type of the failure. The steady-state equations for this model and a simple algorithm to find the steady-state probabilities when $r = 1$ are proposed. The authors also analyze the optimal PM problem to minimize unavailability with respect to λ_m . An extension of this model where $r = 1$ is investigated by Sim and Endrenyi [43]. This paper considers the systems that can be restored to “as good as new” status preventively. It is assumed that the first $s - 1$ PM actions are minimal (i.e., the system is restored to the previous deterioration level), then the following PM is major maintenance where the system is restored to level 0. This system is also subject to Poisson failures; but after a Poisson failure, the system experiences a minimal repair, which is exponentially distributed (i.e., the system is restored to the operable state it was in just before the failure). After a deterioration failure, the system is again overhauled to state 0. A recursive algorithm is proposed to find steady-state probabilities, and closed-form expressions for steady-state probabilities in the case where $s \rightarrow +\infty$ are given. The optimal values of λ_m , which minimize unavailability and average cost, respectively are also discussed.

This line of research is also followed by Chen and Trivedi [44] who consider a model where the holding times are dependent on the deterioration level and each inspection takes an exponentially distributed amount of time. It is assumed that the system is inspected after a random period which is exponentially distributed with rate λ_{in} . The applied PM policy can be summarized by the two thresholds

(g, b) as follows: if the observed deterioration level is $i \leq g$ after an inspection, then no maintenance occurs. If the system deterioration level is i with $g < i \leq b$, then the system is restored to level $i - 1$ by minimal maintenance. The system experiences major maintenance when the deterioration level is found to be in i with $b < i \leq M - 1$, by which the system is restored to level 0. If a deterioration failure occurs, the system is overhauled to level 0. Moreover, the system is subject to Poisson failures after which a minimal repair is performed, which restores the system to the level it was in just before the failure. For this model, the authors give closed-form expressions for steady-state probabilities, steady-state availability, and mean time to failure (MTTF). They also numerically analyze the optimal inspection intervals (λ_{in}) minimizing unavailability and average cost respectively, and maximizing MTTF under a target availability constraint. The optimality of such a threshold policy is shown by Chen and Trivedi [45] who analyze numerical examples for the case where the deterioration rate at each level is the same. A similar model where $g = 0$ is analyzed by Amari and McLaughlin [46]. Closed-form expressions for steady-state probabilities and availability are presented and algorithms to solve three optimization problems maximizing the system availability are given. These problems are formulated to find optimal λ_{in} for a given value of b , to find optimal b for a given value of λ_{in} , and to find optimal values of b and λ_{in} .

Minimal repair action may also be applied at any deterioration level of the system. Moustafa *et al.* [47] analyze a model where each holding time follows a general distribution and, at each state transition, one of three possible actions can be chosen: do nothing, minimal maintenance, and replacement. To derive the optimal policy minimizing the expected long-run cost rate, two different approaches are followed. In the first approach, a control-limit policy with two thresholds is determined. The second approach uses the conventional policy iteration algorithm. By numerical examples, it is shown that the optimal policy may not be control-limit and minimal maintenance may not be optimal in any state when the cost and

the time of minimal maintenance increase relative to the cost and the time of replacement respectively. A similar problem for software maintenance is analyzed by Krishnan *et al.* [48] assuming that the state of a software follows a Markov chain with a monotone transition matrix. The decision maker has three options at each decision epoch: do nothing, minor update, and major upgrade (rewrite of the software). Although they show that there exists a state beyond which major upgrade is always optimal, the optimal policy does not necessarily have a control-limit structure. Several situations specific to the software environment are investigated, such as long rewrite periods (more than one decision epoch), major upgrades due to technological advances, and partial rewrite of the software. They also analyze the effect of these situations on major upgrade decisions under some monotonicity assumptions on the cost functions.

Minimal maintenance restores the system to the previous deterioration level in all previously cited papers. An extension of this idea can be repair, by which the system can be restored to any better deterioration level. For example, a rather general policy $R_{ij}(T, N, \alpha)$ for a continuous-time Markovian deteriorating system is proposed and analyzed by Chiang and Yuan [49]. Under this policy, the system is inspected at times $T, 2T, 3T, \dots$ to identify the current deterioration level a of the system. Let m be the number of repairs already undertaken until the inspection time. The maintenance decision will be do nothing if $a \leq i - 1$, or $i \leq a \leq j - 1$ and $m = N$. The system is repaired to a better state if $i \leq a \leq j - 1$ and $m < N$. The next deterioration level of the system after the repair will be determined by the probability matrix α (i.e., the system will be restored to state r with probability α_{ar}). The maintenance decision will be replacement if $j \leq a \leq M$. An algorithm is also proposed to derive the optimal values of i, j , and T for given N and α .

CONIC OPTIMIZATION SOFTWARE

IMRE PÓLIK
Optimization Solver Developer
SAS Institute, Inc., Cary,
North Carolina

PROBLEM DESCRIPTION

Conic optimization solvers target problems of the form

$$\begin{aligned} \min c^T x & \quad \max b^T y \\ Ax = b & \quad A^T y + s = c \\ x \in \mathcal{K} & \quad s \in \mathcal{K}^*, \end{aligned} \quad (1)$$

where $b, y \in \mathbb{R}^m$, $c, x, s \in \mathbb{R}^N$, $A \in \mathbb{R}^{m \times N}$, $\mathcal{K}, \mathcal{K}^* \subset \mathbb{R}^N$, and $\mathcal{K}^*$ is the dual of $\mathcal{K}$. In general, solvers exist if $\mathcal{K}$ is one of, or the product of, a few copies of the following cones:

Nonnegative Orthant: the set of nonnegative vectors, $\mathbb{R}_+^n$.

Lorentz Cone: the set $\mathbb{L}_{n+1} = \{(u_0, u) \in \mathbb{R}_+ \times \mathbb{R}^n : u_0 \geq \|u\|\}$, also called the *quadratic* or *ice-cream* cone.

Rotated Lorentz Cone: the set $\mathbb{L}_{n+1}^r = \{(u_0, u_1, u) \in \mathbb{R}_+ \times \mathbb{R}^n : u_0 u_1 \geq \|u\|^2, u_0 \geq 0\}$.

Positive Semidefinite Cone: the cone $\mathbb{PS}^{n \times n}$ of $n \times n$ real symmetric positive semidefinite matrices.

Complex Hermitian Cone: the cone $n \times n$ complex Hermitian positive semidefinite matrices.

The dimensions of the cones forming the product can be arbitrary. For semidefinite optimization, we need to introduce some special notation, since the variables are

matrices:

$$\begin{aligned} \min C \bullet X & \quad \max b^T y \\ A^{(i)} \bullet X = b_i, i = 1, \dots, m & \quad \sum_{i=1}^m A^{(i)} y_i + S = C \\ X \in \mathbb{PS}^{n \times n} & \quad S \in \mathbb{PS}^{n \times n}, \end{aligned} \quad (2)$$

where $X, S, C, A^{(i)} \in \mathbb{R}^{n \times n}$ and $b, y \in \mathbb{R}^m$. For symmetric matrices U and V , the quantity $U \bullet V = \text{Tr } UV$ is a scalar product defined on symmetric matrices, and is identical to the sum of the componentwise products of the matrix elements.

Very often the matrices $A^{(i)}$ are sparse or have some other special structure, which can be exploited in the algorithms. For general results on the theory and algorithms of conic optimization see Wolkowicz *et al.* [1] and Alizadeh and Goldfarb [2] and the references therein.

ALGORITHMS

Interior-point methods (IPMs) are practically the only choice for semidefinite optimization; most of the existing general-purpose solvers fall into this category. PENSDP [3], a modified version of PENNON is the only general-purpose semidefinite programming solver using a different approach. The implementation of IPMs for conic optimization is more complicated than that for linear optimization, see Borchers [4], Sturm [5], and Toh *et al.* [6] for more details.

General Features and Capabilities

For generic, dense, unstructured semidefinite optimization problems, the following limits apply on a current PC. The number of linear equalities can be $m \leq 10,000$, using a few matrix variables each with dimensions $n_i \leq 5000$. Larger problems can be solved if the problem has some special structure (see

the section titled “Exploiting the Structure of the Problems”). One of the most serious limitations of IPMs for semidefinite programming is that the Newton system tends to be dense even if the original problem is very sparse. This is due to the symmetric scaling introduced in forming the Newton system, and thus it limits the problem size for all methods that actually form the Newton system.

Computational Cost

The computation cost of one iteration of IPMs for the semidefinite programming problem (2) is $\mathcal{O}(m^3 + mn^3 + m^2n^2)$. Depending on the dimensions of the cones, any of the three terms can dominate this expression, since m can be as large as n^2 . If the problem is sparse, then the second and third terms can usually be improved. Alternatively, one can decide not to form the Newton system explicitly, and try to use an iterative method to solve the Newton system without forming it. For second-order cone programming, the cost per iteration for a problem with K cones each of dimension n and m linear equalities is $\mathcal{O}(m^3 + m^2n + Kn^2)$.

Initialization

IPMs require a strictly feasible solution to start the algorithm. However, if the initial solution is far from the central path, then the algorithm will progress very slowly, thus the standard way of initializing is not practical. There are two techniques that are used widely to circumvent this:

Self-Dual Embedding. This technique embeds the original problem in a larger problem, which will have a strictly feasible starting solution on the central path. From the optimal solution of the larger problem one can recover an optimal solution of the original problem, or detect infeasibility [7–12].

Infeasible IPMs. This method [6,13,14] starts with an infeasible solution and works toward improving feasibility and optimality simultaneously.

INPUT FORMATS

Text-Based Formats

One of the earliest input formats for general symmetric cone programming is the one introduced in SDPpack. This solver is now obsolete, but there are converters from the SDPpack format to SeDuMi’s binary format, for example. The sparse SDPA format is a simplified version of the SDPpack format and has become the standard format for general semidefinite programming problems. It is supported by most major solvers and can be easily converted to any other format.

Binary Formats

Solvers that are implemented in Matlab use a standard Matlab data file as their input, but the actual structure of the data is different between solvers. Also, Python-based solvers can store their data in a pickled file. These formats are special to the given solver and are not portable between different solvers.

Modeling Language Support

Unfortunately, commercial modeling languages do not support SDP or cone programming in general, thus limit their use in the commercial sector. Second-order conic optimization is in a slightly better situation, since it is easily formulated, but there are only very few specialized solvers available. Of course, the best way to formulate these problems would be an indirect one: the user should not even know that the problem is solved using conic programming. Robust optimization fits this scheme very well.

There are two widely used open-source modeling languages that support conic optimization: Yalmip (<http://control.ee.ethz.ch/~joloef/yalmip.php>) [15] and CVX (<http://www.stanford.edu/boyd/cvx>) [16,17]. Both these packages are written in Matlab and are interfaced to a variety of conic optimization packages.

COIN Optimization Services

The optimization services (OS) interface in COIN-OR has been extended [18] to model general conic optimization problems. Driven

by applications and practical problems, the format provides ways to express problems in the most natural way, preserving the important structure of the problem.

There are some key differences between problem instance representation in COIN-OR and modeling languages. Modeling languages tend to separate problem data from problem structure, which prevents exploiting the structure lying within the data. In contrast, COIN-OR keeps the data and the structure together.

CURRENT SOFTWARE PACKAGES

In the following we give an overview of the existing cone optimization solvers in alphabetical order.

CPLEX

License: Commercial
Developer: IBM
Capabilities: LP, SOCP
Algorithm: Interior-point method
Special features: Mixed-integer SOCP
Website: <http://www.ibm.com>
Reference: [19]

CPLEX solves second-order conic problems by treating them as special (nonconvex) quadratically constrained optimization problems. It is also one of the few solvers that can handle mixed-integer conic problems.

CSDP

License: Open source
Developer: Brian Borchers
Capabilities: LP, SDP
Algorithm: Interior-point method
Special features: Callable library, Interface to R
Website: <http://projects.coin-or.org/Csdp>
Reference: [4,20]

Parallel versions in both shared [21] and distributed [22] memory configurations are available. CSDP is one of the most advanced solvers, it exploits sparsity in the data matrices $A^{(i)}$.

CVXOPT

License: Open source
Developer: Joachim Dahl, Lieven Vandenbergh
Capabilities: LP, SOCP, SDP
Algorithm: Interior-point method
Special features: Exploits triangular, band, and sparse matrices
Website: <http://abel.ee.ucla.edu/cvxopt/>
Reference: [23]

A fairly new package written in Python, with interfaces to BLAS, LAPACK, sparse matrix libraries, and NumPy. The interfaces can also be used independent of the solver. The package is related to the modeling interface CVXMOD.

DSDP

License: Free
Developer: Steve Benson, Yinyu Ye, and Xiong Zhang
Capabilities: LP, SDP
Algorithm: Interior-point method
Special features: Dual scaling
Website: <http://www.mcs.anl.gov/hs/software/DSDP>
Reference: [24–26]

DSDP is using a dual scaling algorithm and is very efficient when the dual slack variable is sparse. It is the only interior-point implementation that is not using a primal–dual approach.

LMIlab

License: Commercial
Developer: The Mathworks
Capabilities: SDP, LMI
Algorithm: Interior-point method
Special features: Exploiting a Kronecker structure
Website: <http://mathworks.com>
Reference: [27,28]

A Matlab toolbox, later renamed as Robust Control Toolbox, implements a projective algorithm of Nesterov and Nemirovski. This is the only solver that can exploit a Kronecker structure in the problems, and is thus very efficient for optimal control problems, which is its intended use.

LOQO

License: Commercial
 Developer: Robert Vanderbei
 Capabilities: LP, SOCP
 Algorithm: Interior-point method
 Special features: Nonlinear programming
 Website: <http://www.princeton.edu/rvdb/loqo>
 Reference: [29]

LOQO does solve second-order conic optimization problems, but it uses a different approach. It handles the constraint $x_1 - \|x_{2:n}\|_2 \geq 0$ as a general nonlinear constraint, with some extra care taken due to the nondifferentiability of this form. In a similar way, other nonlinear programming solvers can solve SOCO problems at least in principle.

MOSEK

License: Commercial
 Developer: Erling Andersen, Mosek ApS
 Capabilities: LP, SOCP
 Algorithm: Interior-point method
 Special features: Mixed-integer SOCP, nonlinear programming
 Website: <http://www.mosek.com>
 Reference: [30]

MOSEK is a commercial solver for second-order cone and nonlinear problems. It also implements methods to solve mixed-integer problems.

PENSDP

License: Commercial
 Developer: Michal Kočvara
 Capabilities: SDP
 Algorithm: Augmented Lagrangian method
 Special features: Nonlinear SDP
 Website: <http://www.penopt.com/pensdp.html>
 Reference: [3]

A modified version of the PENNON nonlinear programming solver. It is very efficient even for large, sparse problems. This is the only truly general-purpose sonic solver not implementing an IPM.

SDPA

License: Open source
 Developers: Katsuki Fujisawa, Mituhiro Fukuda, Yoshiaki Futakata, Kazuhiro Kobayashi, Masakazu Kojima, Kazuhide Nakata, Maho Nakata, and Makoto Yamashita
 Capabilities: LP, SDP
 Algorithm: Interior-point method
 Special features: Callable library, distributed/shared-memory parallel version, arbitrary precision, sparsity/decomposition
 Website: <http://sdpa.indsys.chuo-u.ac.jp/sdpa/software.html>
 Reference: [31–34]

This is the one of the most advanced packages for semidefinite optimization developed by a large research group in Japan. Efficient parallel versions [35,36] are released for both shared and distributed memory environments. SDPA also implements techniques to decompose sparse problems using matrix completion [37–39] methods. A Matlab interface [40] is also available.

SDPlr

License: Open source
 Developer: Samuel Burer, Renato D.C. Monteiro, and Changhui Choi
 Capabilities: LP, SDP
 Algorithm: Interior-point method
 Special features: Special handling of low-rank coefficient matrices
 Website: <http://dollar.biz.uiowa.edu/sburer/>
 Reference: [41–43]

SDPlr puts special emphasis on exploiting the special low-rank structure of the coefficient matrices and variables. It is very efficient on some special problems, arising from, for example, combinatorics.

SDPT3

License: Open source
 Developer: Kim Toh, Michael J. Todd, and Reha Tütüncü
 Capabilities: LP, SOCP, SDP
 Algorithm: Interior-point method
 Special features: Logarithmic objective function, mixed second-order, and semidefinite constraints
 Website: <http://www.math.nus.edu.sg/~matttohkc/sdpt3.html>
 Reference: [14,44,45]

SDPT3 is written in Matlab and C and can handle problems with mixed nonnegative, second-order, and semidefinite variables. It is also one of the few solvers that can handle a logarithmic term ($\log x$, $\log(x_0 - \|x\|)$ or $\log \det(X)$ depending on the cone) in the objective function simply by internally manipulating the central path parameter in the IPM.

SeDuMi

License: GPL
 Developer: Jos Sturm (1998–2003) and Imre Pólik (since 2005)
 Capabilities: LP, SOCP, SDP

Algorithm: Interior-point method
 Special features: Mixed second-order and semidefinite constraints
 Website: <http://sedumi.ie.lehigh.edu>
 Reference: [46,47]

SeDuMi is one of the first widely successful conic optimization packages. It is written in Matlab and C. Its success is due to its simple user interface and its numerical accuracy and robustness. It is one of the few solvers that use a self-dual embedding instead of an infeasible scheme to initialize the problem. It implements most of the techniques discussed in Ref. 5.

Following the tragic death of Jos Sturm in 2003, the development has been continued by Imre Pólik.

SMCP

License: Open source
 Developers: M. S. Andersen, J. Dahl, and L. Vandenberghe
 Capabilities: LP, SDP
 Algorithm: Interior-point method
 Special features: Special handling of sparse problem data
 Website: <http://abel.ee.ucla.edu/smcp>
 Reference: [48]

It is a new research code, currently in experimental stage. It exploits the sparsity of the problem using chordal graphs and decomposition techniques, and is written in Python and C.

OBSOLETE PACKAGES

Here is a list of some packages that are no longer developed and maintained.

SBmethod

Written in C++ by Christoph Helmberg; it implements a spectral bundle algorithm [49,50] for semidefinite optimization. Not very efficient as a general-purpose solver. Last updated in 2004.

SDPHA

A Matlab package for SDP by F. A. Potra, R. Sheng, and N. Brixius. No longer available.

SDPpack

Launched in 1997, SDPpack was the first package to solve mixed SOCP and SDP problems. It was written by Farid Alizadeh, Jean-Pierre A. Haeberly, Madhu V. Nayakkankuppam, Michael L. Overton, and Stefan Schmieta. It introduced an input format combining both sparse and dense storage schemes. The SDPA format is a simpler version of this, using only sparse data and SDP constraints. It is the only package that uses the AHO scaling technique, developed by three of the authors. Available from <http://cs.nyu.edu/overton/software/sdppack.html>.

Sdpsol

Developed by Wu and Boyd [51,52], it was solving SDPs and determinant maximization problems. It was last updated in 1996. Available from http://www.stanford.edu/boyd/old_software/SDPSOL.html.

SOCP.C

A simple SOCP solver [53] written by Miguel Sousa Lobo, Lieven Vandenberge, Stephen Boyd, and Herve Lebret; it was last updated in 1997. Available from http://www.stanford.edu/boyd/old_software/SOCP.html. This is the only open-source SOCP solver written in C.

SP

SP (<http://www.ee.ucla.edu/vandenbe/sp.html>), released in 1994 by Lieven Vandenberge, was the first freely distributed SDP package. It used a Matlab/C implementation of Nesterov and Todd's primal-dual potential reduction method.

CURRENT RESEARCH TRENDS AND FUTURE DIRECTIONS

It is commonly agreed that for unstructured or fully dense semidefinite optimization problems, IPMs have reached their limits. In what

follows, we give a brief overview of current efforts and research directions.

Parallelization

IPMs are very good candidates for parallelization, as they take very few iterations, while the cost per iteration is typically very high. There are a number of ways to achieve good parallel performance. As most of the operations in an iteration can be written using standard BLAS/LAPACK calls, parallelization is fairly easy for dense data on a shared-memory architecture. Another approach is to use OpenMP to automatically parallelize loops in the code. This approach is used by CSDP [4].

SDPA and CSDP have also been extended to distributed memory clusters [22,32]. These approaches distribute the computation of the Newton system.

Exploiting the Structure of the Problems

Current research focuses on uncovering and exploiting the special structure of the problem to reduce the memory requirements and speed up the computations; see de Klerk [54] for a survey. The following techniques are known.

Chordal Decomposition. These methods [34,36–39] exploit the fact that the dual slack variable S inherits the sparsity structure of the coefficient matrices. By enforcing positive semidefiniteness only on a small number of carefully chosen submatrices of a large sparse matrix, one can make sure that the original matrix can be completed to be positive semidefinite. This can lead to a dramatic reduction of the problem size, but, in general, it may take a long time to find a good decomposition. Also, the decomposed problem may take a longer time to solve, especially if a lot of submatrices are used. On the other hand, the reduced problem can be solved with a standard SDP solver.

SDPA and SMCP are the two solvers that implement this technique in their preprocessing routines. The developers of SDPA have also released a stand-alone converter useable with any compatible solver.

Permutations and Group Symmetry. Even if the problem is fully dense, the structure induced by the physical problem can be exploited to reduce the size of the matrices. In particular, invariance under permutations has been shown to have a dramatic impact. See de Klerk and Sotirov [55] and Bai *et al.* [56] for applications in quadratic assignment and truss-topology design problems.

There is currently no solver that would try to uncover symmetry in the problem. In fact, without knowing anything about the background of a particular problem instance, it is very hard to detect this kind of structure. It is left to the modeler to use the more efficient representation. On the other hand, the reduced problem does not require any special SDP solvers.

There are no known software tools in this area yet.

Special Linear Operators. These techniques exploit the special structure of the linear operator $\mathcal{A}$. In general $\mathcal{A}$ maps an $n \times n$ matrix to an m -dimensional vector, thus its size is mn^2 and it takes $\mathcal{O}(mn^2)$ operations to apply it to an $n \times n$ matrix. There are some cases when the structure of the operator allows to save in both the storage and computational cost. A few examples are as follows:

Kronecker Products. If $\mathcal{A}(X) = AXB$ in problem (2), then $\mathcal{A}$ is mapping an $n \times n$ matrix to another $n \times n$ matrix. In general, such an operator is represented by the Kronecker product $B^T \otimes A$, which is an $n^2 \times n^2$ matrix. This only allows problems with n at most 100. Moreover, not only we can save in storage, but this special structure can also be exploited inside the IPM to obtain an $\mathcal{O}(n^4)$ cost per iteration instead of the standard $\mathcal{O}(n^6)$. This structure is very common in optimal control problems [57].

Low-Rank Coefficients. If the coefficient matrices A_i are of low rank, then $A_i \bullet X$ can be simplified quite a bit. For example, if $A_i = aa^T$, then $A_i \bullet X = a^T Aa$, and also this structure can be exploited inside the IPM to

speed up the computation of the Newton system. The solvers LMilab [27], SDPlr [41], and modified versions of CSDP [22] can take advantage of this format.

This technique faces a few challenges. First, it is not immediately clear how structures like this can be expressed in the existing input formats. Some tried to modify the SDPA format to accommodate low-rank coefficient matrices [22]. Modeling systems CVX and Yalmip can express these problems, but they convert them into standard SDP form before passing them on to the solvers. The extension of COIN-OR [18] to cone programming gives both the modeler and the solver access to this structure.

The second problem is that one needs to modify the solvers to be able to exploit these kinds of structures. LMilab was created with this goal in mind and it remains a very efficient solver for problems in control theory as part of the Robust Control Toolbox in Matlab.

Graph Problems. As combinatorial optimization and graph theory is a fruitful area of application for SDP, it is not surprising that problems defined over a graph have a very special structure. In fact, it is possible to rewrite the internal computations of an IPM in terms of the graph data. SDPlr is currently the only solver that can exploit this structure. This article is closely related to the following articles in the encyclopaedia are *Interior-Point Linear Programming Solvers* and *Semidefinite Optimization Applications*.

CONSERVATION LAWS AND RELATED APPLICATIONS

JOSÉ NIÑO-MORA

Department of Statistics, Carlos III
University of Madrid, Madrid,
Spain

THE PRINCIPLE OF WORK CONSERVATION

Consider a multiclass G/G/1 queue, where a single server attends a finite number n of customer classes labeled by $k \in N \triangleq \{1, \dots, n\}$. Class k customers arrive to the system at rate λ_k with identically distributed interarrival times, while their service requirements are drawn from a distribution having finite mean $1/\mu_k$. No independence assumptions are made on interarrival and service time processes. The stability condition requiring that the system's utilization factor or traffic intensity be less than unity, $\rho \triangleq \sum_{k \in N} \rho_k < 1$, is assumed to hold, where $\rho_k \triangleq \lambda_k/\mu_k$ is the traffic intensity for class k .

In order to determine how to operate such a system, a scheduling policy or service discipline (see *Queueing Disciplines*) must be adopted, which prescribes the priority order in which customers are to be selected for service. Suppose that the system is operated under a scheduling policy that is *work-conserving*, that is, it neither allows the server to sit idle while there are customers waiting, nor does it affect the total service requirement or the arrival time of any customer. Consider the *unfinished work* (also called the *work-in-system* or *workload*) process $U(t)$, which keeps track of the total remaining service time due to customers in the system at each time $t \geq 0$. The evolution over time of such a process can be described as follows: at each arrival epoch, the process has an upward jump of magnitude equal to the arriving customer's service requirement; while the system is nonempty, the process decreases linearly at unit rate; and,

upon hitting zero, it remains there until a customer arrives. The *principle of work conservation*, which follows immediately from the above, states that the unfinished work process $U(t)$ is sample-path invariant under work-conserving scheduling policies.

Further, classic results on the G/G/1 (see *The G/G/1 Queue*) queue ensure existence and uniqueness of a stationary or steady-state distribution for the process $U(t)$, which will have a finite mean $\bar{U}$, provided the service time distribution of each class k has a finite second moment $m_k^{(2)}$. The latter assumption will be adopted in what follows.

KLEINROCK'S CONSERVATION LAW FOR MEAN WAITING TIMES

Consider now a multiclass M/G/1 queue (see *The M/G/1 Queue*) where customer arrival streams are Poisson and all interarrival and service times are mutually independent. Attention is further restricted to the class Π of *admissible* policies that are (i) *work-conserving*; (ii) *nonanticipative* or history-dependent, that is, decisions at any given time can only be based on current or past system information, but not on future information such as future arrival times or remaining service requirements of customers who have not yet departed from the system; (iii) *ergodic*, that is, they induce on system processes, such as the number of customers in system for each class, steady-state distributions with finite means that match the corresponding sample-path averages; and (iv) either *nonpreemptive*, that is, the server allocates its full service capacity to customers one at a time and without interruptions; or (iv) in the multiclass M/M/1 case, *preemptive* of the *preemptive-resume* type, that is the server can temporarily abandon the customer it was serving to attend another customer, continuing later service of the preempted customer at the point it was left off.

Drawing on the principle of work conservation for the unfinished work process and on

Little's law (see **Little's Law and Related Results**) [1], Kleinrock first established in Refs 2 and 3 that, if such a system is operated under an admissible scheduling policy $\pi \in \Pi$, the vector $\bar{\mathbf{W}}^\pi = (\bar{W}_k^\pi)_{k \in N}$ of attained steady-state mean waiting times for the customer classes satisfies a linear equality constraint of the form

$$\sum_{k \in N} \rho_k \bar{W}_k^\pi = g(N),$$

where $g(N) \triangleq \bar{U} - \bar{V} = \rho \bar{V} / (1 - \rho)$ is a constant and

$$\bar{V} \triangleq \frac{1}{2} \sum_{k \in N} \lambda_k m_k^{(2)} = \sum_{k \in N} \rho_k (m_k^{(2)} \mu_k / 2)$$

is the steady-state mean residual time of the customer found in service by a random arrival. Such an invariance relation was termed by Kleinrock a (work) *conservation law*.

An early application of such a conservation law to the analysis of a multiclass M/M/1 queue with delay-dependent priorities is given in Ref. 4. In Ref. 5, pp. 125–126 the conservation law is used to obtain the optimal admissible scheduling policy for operating a multiclass M/G/1 queue as above, where class k customers incur linear holding costs at rate c_k per unit time and the objective is to minimize the steady-state mean cost rate. For such a system, Cox and Smith [6, pp. 84–85] first showed by an interchange argument that among static nonpreemptive priority policies—which assign a fixed priority ranking to the customer classes, as in Ref. 7, an *index policy* is optimal: the so-called *$c\mu$ -rule*, which awards higher priority to classes with larger values of the priority index $c_k \mu_k$. The optimality of the $c\mu$ rule in the class of work-conserving nonpreemptive stationary policies, which make decisions based on the current state, was established in Ref. 8.

The scope of the conservation law is extended in Ref. 9 to a nonpreemptive multiclass G/G/1 queue without independence assumptions on interarrival and service times, with $g(N) \triangleq \bar{U} - \bar{V}$ and $\bar{V}$ as above. Such early results are reviewed in Ref. 5, Section 3.4.

It must be emphasized that, as pointed out in Ref. 10, p. 175, although the nonanticipativity assumption on admissible scheduling policies is not explicitly mentioned in such early works, it is, however, critical to the validity of the above conservation laws.

Extensions of the conservation law are presented in Ref. 11, pp. 431–435 to multiclass multiserver G/G/m queues (see **The G/G/s Queue**), where for each class arrival times form a renewal process and service times are i.i.d., having the same distribution for all classes if $m \geq 2$. Different formulations of the law are given under nonpreemptive and under preemptive-resume policies.

While the above works have focused on continuous-time queueing systems where customers arrive one at a time, conservation laws for multiclass queues in discrete time with batch arrivals are presented in Refs 12 and 13.

WORK CONSERVATION LAWS FOR CONDITIONAL MEAN WAITING TIMES

For queueing systems that are operated under scheduling policies that are of processor-sharing type [5, Chapter 4] (i.e., the server's capacity may be simultaneously shared by multiple customers at given rates), which may also be preemptive (e.g., the foreground-background (FB) or least-attended service (LAS) rule [14]) or anticipative (e.g., the shortest remaining processing time (SRPT) rule [15] or the shortest job first (SJF) rule [16]), an appropriate measure of performance is the steady-state conditional mean response time $\bar{T}^\pi(x)$ for a customer with total service requirement x , as well as the conditional mean waiting time $\bar{W}^\pi(x) \triangleq \bar{T}^\pi(x) - x$.

For a single-class M/G/1 queue operated under any work-conserving processor-sharing nonanticipative policy π , Kleinrock *et al.* [17] first showed that the conditional mean waiting times $\bar{W}^\pi(x)$ obey a conservation law of the form

$$\int_0^\infty \bar{W}^\pi(x) (1 - B(x)) dx = g,$$

where $B(x)$ is the distribution function of service times and $g \triangleq (1/2)\rho m^{(2)}/(1 - \rho)$.

Such a result is used in Refs 17 and 18 to obtain tight bounds, via mathematical programming, on the performance of processor-sharing scheduling policies.

The scope of such a conservation law for processor-sharing systems is extended in Ref. 19 to G/G/1 queues under work-conserving anticipative policies, incorporating the mean conditional time $\bar{T}^\pi(u, x)$ that a customer with total service time x spends in the system to obtain $u \leq x$ units of service.

Conservation laws for conditional mean waiting times for multiserver G/G/m queues are obtained in Ref. 11, pp. 425–427 under nonanticipative processor-sharing policies, which, if $m \geq 2$, are further required to not distinguish between customers on the basis of their service time characteristics.

Kleinrock's conservation law for conditional mean waiting times has been used in Ref. 20 to analyze a processor-sharing queue with batch arrivals, and the results are applied to analyze a multiclass version of multilevel processor-sharing type.

Work conservation laws for a multiclass queue under discriminatory processor-sharing scheduling [21] are obtained in Ref. 22. The literature in the area is reviewed in Ref. 23, which presents a unifying version of the work conservation law.

ACHIEVABLE PERFORMANCE CHARACTERIZATION AND OPTIMIZATION VIA CONSERVATION LAWS

Kleinrock's conservation law implies that the performance vectors $\bar{\mathbf{W}}^\pi$ of mean waiting times which are achieved under admissible scheduling policies π lie on a hyperplane in $\mathbb{R}^n$. Such a geometric viewpoint leads to the following question: What are the constraints characterizing the (achievable) *performance region* $R = \{\bar{\mathbf{W}}^\pi : \pi \in \Pi\}$, which is spanned by achievable performance vectors $\bar{\mathbf{W}}^\pi$ as the scheduling policy π ranges over all admissible policies. Such an issue was first resolved in Ref. 24 for a preemptive multiclass M/M/1 queue under a modified class of admissible policies having a regenerative structure (see **Markov Regenerative Processes**), in which server allocation decisions are required to

depend on the current busy period's history. The performance region under the resulting class of admissible policies is shown to be the convex polytope (i.e., bounded polyhedron) determined by Kleinrock's conservation law (see **Basic Polyhedral Theory**), along with a family of linear inequality constraints of the form

$$\sum_{k \in S} \rho_k \bar{W}_k^\pi \geq g(S),$$

where $S \subset N$ ranges over all nonempty subsets of customer classes and $g(S)$ is a positive constant that depends on S .

The above inequality for subset S holds with equality under admissible policies that give higher priority to customers whose classes belong to S , which leads to the result that the vertices of the performance polytope are the performance vectors achieved by the $n!$ static priority rules. These results are used to synthesize policies that attain given achievable performance vectors.

Similar results are obtained for multiclass nonpreemptive M/G/1 queues in Ref. 10, Chapter 6. These works further address the synthesis problem, either via mixing policies, which at the start of each busy period draw at random from a certain distribution a static priority rule to be used during the period, or via other more convenient (in terms of reduced variances) complete parameterized families of scheduling policies [25].

The performance region is similarly characterized in Ref. 26 for an exponential multiclass finite-source queue, where the performance vector consists of the utilization factors for the customer classes.

In Ref. 27 an analogous approach is deployed to address the problem of characterizing the class of achievable conditional delay functions $\bar{W}^\pi(x)$ for a nonpreemptive M/G/1 queue, under admissible policies that can make use of exact knowledge of customer processing times.

In Ref. 28 sufficient conditions are given under which the performance region of a nonpreemptive M/G/m queue is a polytope of the type identified in Ref. 24; see also the article titled **The M/G/s Queue** in this encyclopedia. Similar results are obtained for preemptive multiclass G/G/m queues in

Ref. 29; see also the article titled *The G/G/s Queue* in this encyclopedia. The required conditions include verification that the right-hand side set function $g(S)$ is supermodular [30]. Under such conditions, the achievable performance polytope is the base of a polymatroid, a much studied polyhedron in polyhedral combinatorics (see *Basic Polyhedral Theory*) introduced in Ref. 31, which possesses strong structural and algorithmic properties and explains the optimality of the greedy algorithm in a wide range of resource allocation problems. The papers [28,29] further exploit such a polyhedral structure to obtain optimal policies for separable convex performance objectives.

Such early results on achievable performance characterization are unified and new results are obtained via the axiomatic framework of so-called *strong (work) conservation laws* introduced in Ref. 32, which gives simpler sufficient conditions, ensuring that the performance region is the base of a polymatroid, with the ensuing algorithmic consequences for performance optimization. Most notably, such conditions do not require *a priori* verification of supermodularity for the right-hand side functions $g(S)$ in the conservation laws. Instead, it suffices to establish that, for any subset S of classes, the above inequality holds, and equality is achieved by any static priority policy that gives higher priority to customers whose classes belong to S .

The polymatroidal structure of the performance region under conservation laws allows deployment of powerful polyhedral combinatorics methods for analyzing algorithmic performance problems, such as determining whether a given performance vector is achievable [33].

The need in some applications to use adaptive policies, which may be nonergodic or for which ergodicity is hard to establish, motivates Georgiadis and Viniotis [34] to extend conservation laws to a multiclass G/G/1 queue under a broader class of admissible policies, which neither assume a regenerative structure nor convergence to steady state. For the multiclass M/G/1 case, extensions of the conservation laws are given in terms of limits of linear combinations of

sample averages. Such results are used to design lexicographically optimal adaptive policies for M/G/1 queues in Ref. 35.

CONSERVATION LAWS AND CONSTRAINED PERFORMANCE OPTIMIZATION

The results on polymatroidal structure of the achievable performance region via conservation laws can be exploited to obtain tractable scheduling policies that optimize linear performance objectives under linear performance constraints.

In Ref. 36, a multiclass M/G/1 queue is used to model a telecommunication system where customer classes correspond to heterogeneous traffic classes, which can be of interactive or noninteractive type. The problem of finding a scheduling policy that minimizes a weighted mean delay objective for noninteractive classes is addressed, subject to constraints that require the mean delays for interactive classes to not exceed given thresholds. Under appropriate conditions, a tractable optimal policy is obtained using linear programming (LP) methods that exploit the polymatroidal formulation obtained via conservation laws. An optimal policy is obtained that partitions the classes into several groups and uses a static priority rule among the groups. Within each group, an appropriate randomization among priority rules is employed.

Such an approach is extended in Ref. 37 to constrained optimization in a multiclass Jackson queueing network (see *The G/G/s Queue*) populated by interactive and noninteractive traffic classes, for which the required conservation laws are established.

The problem of optimal scheduling of a multiclass M/G/1 queueing model of a flexible manufacturing station subject to upper bounds on average delays for job classes, relative to a nonlinear cost objective, is addressed in Ref. 38. Drawing on the polymatroidal achievable performance results, an optimal policy is constructed having a similar structure as in the two previous models discussed above.

In Ref. 39 conservation laws are used to address the problem of joint design of a static load balancing rule and a dynamic local scheduling policy for a queueing model of a distributed computer system. Each of a set of host computers generates a collection of dedicated traffic classes, which can only be processed at the host and are subject to upper bound constraints on their average response times. In addition, hosts generate a generic traffic class, which can be allocated to be processed at any host. For a given static allocation of generic jobs to hosts, each host behaves as a multiclass M/G/1 queue subject to average performance constraints on its dedicated classes. The polymatroidal characterization of the corresponding performance region due to satisfaction of conservation laws is exploited to obtain a tractable policy that minimizes the average response time of generic jobs, subject to given average response bounds on dedicated jobs.

A related although distinct approach is deployed in Ref. 40 to address the constrained optimization of a discrete-time preemptive multiclass single-server queue with geometric service time distributions, where policies are not required to be ergodic. Using Lagrangian methods, the performance region is (implicitly) characterized in terms of that achieved under the class of time-sharing policies, which do not use randomization and may be nonregenerative. Further discussion regarding how to obtain an optimal time-sharing policy that satisfies linear performance constraints follows.

GENERALIZED CONSERVATION LAWS AND OPTIMIZATION FOR KLIMOV'S AND BANDIT MODELS

Klimov's model [41,42] is an extension of the nonpreemptive multiclass M/G/1 queue, which incorporates instantaneous Bernoulli feedback between customer classes (see **Klimov's Model**). Thus, when a class k customer completes service, it is fed back to the system as a class l customer with probability p_{kl} , and leaves the system with probability p_{k0} . In his ground-breaking paper [41], Klimov addressed the problem of

finding an optimal scheduling policy relative to a linear average holding cost objective. He established the optimality of a static priority rule, where priority ranking is determined by an index attached to each class, with larger index values awarding higher priority. For such a purpose, he used flow balance arguments to obtain an LP formulation of the optimal scheduling problem, whose analysis yields an efficient index algorithm along with an optimality proof for the resulting index rule.

An exact polyhedral characterization of the performance region for Klimov's model under ergodic policies, obtained via the principle of work conservation, was first presented in Ref. 43. The linear constraints characterizing the region of achievable mean delays $\bar{\mathbf{W}}^\pi$ consist of an equality constraint of the form

$$\sum_{k \in N} \rho_k^N \bar{W}_k^\pi = g(N),$$

along with a family of inequality constraints of the form

$$\sum_{k \in S} \rho_k^S \bar{W}_k^\pi \geq g(S)$$

for nonempty subsets $S \subset N$ of customer classes, where the ρ_k^N and ρ_k^S are positive workload coefficients. The resulting polytope is no longer the base of a polymatroid, but that of a new type of polytope, a so-called *extended* polymatroid, which also possesses strong structural and algorithmic properties, as elucidated in Ref. 44. Further extensions of conservation laws under nonergodic policies are introduced in Ref. 43 and further developed in Ref. 45, where they are used to obtain adaptive policies for optimizing nonlinear performance objectives in the Klimov model.

The axiomatic framework of strong conservation laws for multiclass queues without feedback in Ref. 32 is extended in Ref. 46 to the framework of generalized conservation laws, which have the form indicated above for the Klimov model. Further, in Ref. 46 such a framework is deployed to obtain the polyhedral performance region of the more general branching bandit model [47,48], both

under average and discounted performance measures, including as a special case the classic multiarmed bandit problem [49]. A new proof is thus obtained via conservation laws and polyhedral LP methods for the optimality of index policies in such classic problems.

The problem of finding an optimal scheduling policy for the branching bandit problem under the average criterion under linear performance constraints, and hence for the Klimov model with such constraints as a special case, is addressed in Ref. 50 via LP methods, exploiting the extension to branching bandits of the LP formulation originally introduced in Ref. 41. Unlike the LP formulation given in Ref. 46, which has $2^n - 1$ constraints on n variables, that in Refs 41 and 50 has $O(n^2)$ constraints on n^2 variables, which renders it more amenable to direct computational approaches.

In Refs 51 and 52 the properties of generalized conservation laws and extended polymatroids are further reviewed and developed, including connections with submodularity and the efficient algorithmic treatment of side constraints. The reader is referred to Ref. 53, Chapter 11 for an accessible textbook account of such methods.

PSEUDOCONSERVATION LAWS FOR MULTICLASS QUEUES WITH SETUP TIMES

In some applications of multiclass queues, such as in flexible manufacturing systems or in computer communication networks, the assumption that the server can switch instantaneously from one class to another is not realistic. This motivates incorporation of random setup times, which are incurred before the server starts to service a class of customers after leaving another class. A major area of application in communication networks is that of polling systems. See, for example, the review paper [54].

A policy π for dynamic server allocation in a multiclass queue with setup times must specify: (i) a service discipline for determining when the server should leave the class it is currently allocated to (e.g., exhaustive service, gated service, etc.); and (ii) a routing rule, which specifies the class to visit

next after leaving a class (e.g., cyclic routing, routing according to a polling table, etc.). Most research in the area has focused on the performance analysis of particular policies, such as cyclic routing with exhaustive service [55]. Early work on optimal dynamic control of polling systems is surveyed in Ref. 56.

For such systems, the principle of work conservation does not apply, since the time intervals spent by the server in switching from one class to another represents a creation of work. Yet, researchers have identified in a variety of such systems so-called pseudoconservation laws. For a multiclass M/G/1 queue as in the section titled “Kleinrock’s Conservation Law for Mean Waiting Times”, which further incorporates random setup times for each class, a pseudoconservation law is an invariance identity of the form

$$\sum_{k \in N} \rho_k \bar{W}_k^\pi = g(N) + \bar{Y}^\pi,$$

where $\bar{Y}^\pi$ is a policy-dependent term related to the expected amount of work in the system at a random time during setups. Such expressions have been used to provide qualitative insight into system behavior, and in approximate performance analyses of complex systems.

Pseudoconservation laws were first identified in Refs 57–60, under cyclic routing policies where each class is serviced according to a certain type of service rule. In Ref. 61 such results are extended to cyclic routing and mixed service (i.e., possibly a different rule is used for each class) policies, and the connection is established between such laws and the stochastic work decomposition results for queues with vacations (cf. Refs 62 and 63). The latter state that, under certain conditions, the steady-state amount of work in a system with service interruptions can be decomposed as the sum of two independent random variables: the amount of work in a corresponding system without interruptions, and the amount of work-in-system at an arbitrary epoch in a switching interval.

Pseudoconservation laws for cyclic multiclass discrete-time queues with setup

times are given in Ref. 64, and for systems where routing is specified by a noncyclic polling table in Ref. 65. Such early work is surveyed in Ref. 66. In Ref. 67, corresponding results are obtained in the setting of a version of Klimov's model, which incorporates setup times under cyclic policies. Pseudoconservation laws are obtained under static priority rules in Refs 68 and 69, and under more general priority rules in Ref. 70 for systems with batch arrivals. In Ref. 71, general pseudoconservation laws are obtained for Klimov's model with setup times under arbitrary dynamic policies, by reformulating linear flow balance constraints on performance measures in terms of workloads. Such laws are used to obtain a polyhedral LP relaxation of the performance region yielding bounds on optimal performance, determined by constraints of the form

$$\sum_{k \in S} \rho_k^S \bar{W}_k^\pi \geq f(S),$$

where $S \subseteq N$ ranges over subsets of customer classes and $f(S)$ is a positive constant that depends on S .

CONSERVATION LAWS AND PERFORMANCE BOUNDS FOR MULTICLASS QUEUEING NETWORKS

Multiclass multistation queueing networks (see **Multiclass Queueing Network Models**) are powerful models for a wide variety of real systems, most notably computer communication and flexible manufacturing networks, where multiple traffic classes vie for access to system resources (e.g., servers' attention). The performance of such systems, such as the vector of average response times for each class, can be significantly affected by the choice of control policy adopted for dynamic resource allocation (e.g., scheduling, routing). Yet, the exact performance analysis of even relatively simple policies that discriminate among customer classes appears both analytically and computationally intractable. As a result, simulation has been the primary tool for investigating such system models. This motivates the interest of obtaining tractable bounds on

achievable performance, which can be used to assess the degree of suboptimality of proposed policies (see **Performance Bounds in Queueing Networks, The G/G/s Queue**).

A relaxed LP formulation for scheduling problems on such networks, which extends Klimov's original LP formulation [41] and furnishes tractable bounds on optimal performance, was introduced in Ref. 72. A different approach to obtain such bounds for Markovian multiclass queueing networks based on LP relaxations is proposed in Ref. 73, based on Lyapunov function ideas, along with stronger bounds based on nonlinear convex and semidefinite programming constraints. Similar LP relaxations are proposed in Ref. 74, drawing on an analysis of quadratic functions of workload. The bounds are shown to yield good approximations in some networks. The LP equality constraints in both papers are derived in Ref. 75 via flow balance identities by using Palm calculus (cf. Ref. 76). The latter paper further obtains linear and convex nonlinear and semidefinite programming relaxations for Markovian multiclass queueing networks with random setup times.

A polymatroidal LP relaxation of the performance region is used to analyze the version of Klimov's model with multiple exponential servers in parallel in Ref. 77. The LP constraints are obtained in terms of approximate work conservation laws, which emerge by reformulating flow balance identities. The LP relaxation is used to obtain closed-form bounds on the suboptimality gap of the parallel version of Klimov's priority-index rule, which are tight enough to establish the asymptotic optimality of such a rule in the heavy-traffic regime.

The approach of addressing performance optimization problems in stochastic systems via exact or relaxed mathematical programming formulations of their performance regions has been termed the *achievable region approach*. An accessible presentation along with further examples of deployment are given in Ref. 78, followed by discussions by several researchers.

While most work on conservation laws has focused on steady-state expectations, it is of interest in some applications to exploit the sample-path nature of the principle of work conservation. This has been done in Ref. 79, both for certain examples of multiclass queueing systems and for some stochastic fluid models of such systems.

The analysis of a fluid model of the Klimov network via sample-path work conservation and the achievable region approach is carried out in Ref. 80, where it is shown that a priority-index scheduling rule is optimal for linear performance objectives. The achievable region formulation of the fluid Klimov network is employed to obtain a tractable scheduling control policy for a linear performance objective under side constraints in Ref. 81.

A number of papers have identified and exploited work conservation laws to analyze and optimize the performance of more specific complex queueing models arising in communication networks. Some examples of relevant work in the area are Refs 82–94.

PARTIAL CONSERVATION LAWS AND INDEXABILITY FOR RESTLESS BANDIT MODELS

Multiarmed restless bandits are an extension of classic (nonrestless) multiarmed bandits, concerning the optimal dynamic allocation of effort to multiple stochastic projects, modeled as binary-action (active/passive) Markov decision processes. In the restless model, projects can change state under passive dynamics, while in the classic model the states of passive projects remain frozen. Many dynamic resource allocation problems in queueing systems can be readily formulated as multiarmed restless bandit problems.

In Ref. 95, Whittle introduced the model and proposed a tractable heuristic priority-index rule via a Lagrangian relaxation approach, which further yields a bound on optimal performance, as the problem is generally intractable. Unlike its counterpart for classic bandits, however, such an index only exists for the limited class of the

so-called indexable restless bandits. In Ref. 96 the asymptotic optimality of the resulting index policy is established under certain conditions. In Ref. 97, a hierarchy of LP relaxations is introduced using flow balance equations, which yield tighter performance bounds at increasing computational expense.

The issues of finding simple sufficient conditions for indexability and index computation were first addressed in Ref. 98 via the introduction of so-called partial (work) conservation laws, which extend the generalized conservation laws framework in Ref. 46. Such laws require the satisfaction by performance measures x_k^π of an equality constraint

$$\sum_{k \in N} \rho_k^N x_k^\pi = g(N),$$

as well as of inequality constraints

$$\sum_{k \in S} \rho_k^S x_k^\pi \geq g(S),$$

where the class subsets S are only required to range over a typically restricted family $\mathcal{F}$ of customer classes satisfying appropriate connectivity requirements. Such a framework is designed to exploit special structure and insight on the model at hand, as the family $\mathcal{F}$ must be guessed in advance. Satisfaction of partial conservation laws yields a relaxed LP formulation of the achievable performance region, which can be used to obtain optimal policies for a limited range of linear performance objectives. Such conservation laws, which are applied to discounted and long-run average expected occupation measures of single restless bandits, allow to establish the existence of index-type solutions, which are consistent with a prespecified structure on policies (e.g., threshold policies), and further yield an efficient adaptive-greedy index-computing algorithm, by exploiting the underlying polyhedral LP formulation. Such a framework of partial conservation laws is further developed in Ref. 99, where applications are given to dynamic admission control and routing to parallel queues, and in Ref. 100, which presents an application to scheduling a multiclass make-to-order/make-to-stock M/G/1 queue under convex

stock holding and backorder costs. See also Refs 101–104. These and other applications of restless bandit indexation and partial conservation laws are reviewed in Ref. 105.

Bologna, Italy

INTRODUCTION

Constraint programming (CP) [1–4] is a powerful paradigm for solving combinatorial decision and optimization problems. The first CP languages were based on logic programming. Constraint logic programming has been proposed as a general scheme [5] that can be instantiated on many different sorts, namely, real numbers, integer, pseudo-Boolean, sets, trees, and so on. The most successful instantiation of the scheme is the one on finite domain that has been used to solve combinatorial problems. In the rest of the article, we will focus on constraint programming on finite domains (CP(FD)), also referred to as *constraint programming*.

In CP, problems are modeled using variables ranging on a finite domain of integers and constraints over subsets of these variables. The CP solving methodology interleaves constraint propagation and search. Constraint propagation is an inference mechanism based on domain filtering. Each constraint embeds a filtering algorithm that removes values that cannot appear in any consistent solution. Since variables are involved in several constraints, domain updates are propagated to the other constraints whose filtering algorithms are triggered and possibly remove other domain values in an iterative manner. Unfortunately, removing all inconsistent values has the same complexity of solving the original problem; for this reason, propagation may be incomplete: all removed values are certainly inconsistent, but not all values left are guaranteed to be consistent. Therefore, search is needed to explore the remaining part of the search tree. At each node, propagation

is again triggered until either a solution is found or a failure is reached.

The solution methods of CP and mathematical programming (MP) have complementary strengths. Recent research shows that these strengths can be profitably combined in hybrid algorithms. On one hand CP is very effective for the so called *feasibility reasoning*. Constraint propagation enables to avoid searching in infeasible regions of the search space. In addition, being constraint propagation a mechanism that is based on constraint interaction, adding side constraints to a model in general improves the performance of a constraint solver. On the other hand, MP is effective for the so called *optimality reasoning*. The use of relaxation and the definition of cutting planes enable to avoid searching in suboptimal regions of the search space. In addition, many structured problems have been deeply analyzed in operations research (OR) and specific cutting planes have been devised to tighten the problem relaxation.

Therefore, CP and MP have complementary strength and can be conveniently merged to exploit the advantages of both [6–9]. In this survey we adopt a CP perspective and we focus mainly on the CP literature. Therefore, MP techniques assist the CP solving process, for example, filtering and bounding. However, there is a different perspective: recently some notable contributions from the OR literature propose that CP can contribute in a MP algorithm, as happens in SCIP (solving constraint integer programs) [10] or that CP and MP can contribute to an equal basis to the solving process as happens in SIMPL [11], but these approaches are out of the scope of this article.

From a CP perspective, one very effective technique for combining CP and MP is to use a CP solver as the master solver and integrate MP algorithms within CP global constraints. Global constraints are very powerful constructs that compactly represent a set of primitive constraints. Global constraints are not only syntactic sugar, but also embed

filtering algorithms that reason globally and enable powerful filtering. There are several ways to integrate filtering algorithms coming from MP into global constraints: either using graph-based algorithms or dynamic programming for achieving arc-consistency, or embedding relaxations into the constraint or providing a linearization of the constraint that can be solved by a linear programming solver as happens in MP Branch and Bound.

Another way to combine the strength of CP and MP is to decompose the problem and to use the most effective solver on each component. Two notable examples of this integration are logic based Benders decomposition and CP based column generation. In both cases, depending on the specific structure of the component derived from decomposition, the most suitable solver is used. For example, side constraints are more effectively faced with CP tools, while for structured problems the most efficient technique is MP.

Search strategies have been widely studied in CP. Information coming from relaxation have been used for improving the search by driving it toward promising regions in terms of costs.

Nowadays, many commercial and academic tools have been developed for designing hybrid algorithms. We will provide in this article, a short description of the ones developed in the CP community.

CONSTRAINT PROGRAMMING

CP on finite domains has been recognized as a suitable modeling and solving tool to solve combinatorial problems. In this section, we provide some basic notions on modeling aspects, constraint propagation, and search and optimization.

The CP modeling and solving activity is highly influenced by the Artificial Intelligence area on Constraint Satisfaction Problems, CSPs (see the book by Tsang [12]). A CSP is a triple $\langle V, D, C \rangle$ where V is a set of variables $X_1, \dots, X_n$, D is a set of finite domains $D(X_1), \dots, D(X_n)$ representing the possible values that variables can assume, and C is a set of constraints $C_1, \dots, C_k$. Each constraint involves a set of variables $V' \subseteq$

V and defines a subset of the Cartesian products of the corresponding domains containing feasible value tuples. Therefore, constraints limit the values that variables can simultaneously assume.

A solution to a CSP is an assignment of values to variables which is consistent with constraints. If we are interested in the optimal solution instead of a feasible one, an objective function can be imposed on problem variables.

There exists a one to one mapping between CSP concepts and CP on finite domains syntactic structures. Thus, CP benefits from and extends results achieved for CSPs.

Modeling a Problem

A CP model contains variables ranging on a finite domain of values and a set of constraints involving those variables. Values can be objects of arbitrary type, but in general these languages manage finite domains of integers. Given a variable X its domain $D(X)$ denotes values that variables can assume. For example, in a scheduling application, if *Start* is a variable representing the starting time of an activity, its domain can be the schedule horizon, for example, $Start :: [1..100]$. This (unary) constraint states that variable *Start* can assume one of the integer values between 1 and 100. For another example, if a given variable *Pos* represents the position in a sequence of a given object, and positions available for the object are only 3, 5, and 9, we can express this constraint with a domain variable $Pos :: [3, 5, 9]$.

A constraint C on a set of variables $\{X_1, \dots, X_n\}$ is defined as a subset of the Cartesian product of their domains, that is, $C \subseteq D(X_1) \times D(X_2) \times \dots \times D(X_k)$. A tuple $(d_1, d_2, \dots, d_k) \in C$ is said to be a solution of C . A value $d \in D(X_i)$ is said to be inconsistent with respect to (w.r.t.) C if it does not belong to any solution of C .

Constraints can be either mathematical or symbolic constraints. Mathematical constraints are the usual relations among integer variables (i.e., $=$, $\neq$, $\leq$, $<$, $\geq$, $>$). An example of mathematical constraint is the following: if two activities i and j characterized by starting times S_i and S_j and durations D_i

and D_j are linked by a precedence constraint stating that activity i should be executed before activity j , the following constraint can be imposed, $S_i + D_i \leq S_j$. Symbolic constraints, called also *global constraints*, are more expressive and powerful constraints embedding constraint-dependent filtering algorithms. A typical global constraint is the *alldifferent* ($[X_1, \dots, X_n]$) [13], available in most CP solvers like CHIP [14], ECLⁱPS^e [15], and ILOG Solver [16]. Declaratively, the constraint *alldifferent* ($[X_1, \dots, X_n]$), holds if and only if all variables are assigned to a different value. Thus, it is declaratively equivalent to a set of $n * (n - 1)/2$ binary constraints. However, it is more compact allowing more concise models and it embeds a specialized filtering algorithm, which we will discuss later in the article.

An extension of the *alldifferent* is the *global cardinality constraint* [17]

$$gcc([X_1, \dots, X_n], [v_1, \dots, v_m], \\ [l_1, \dots, l_m], [u_1, \dots, u_m]),$$

which holds if and only if the number of variables in $[X_1, \dots, X_n]$ which assume value v_i is within l_i and u_i .

The objective function in a CP program is represented by a domain variable. For example, if we have to minimize the makespan in a scheduling problem (i.e., its total duration), we have to minimize the ending time of the last activity. Therefore, we have to minimize $Z = \max_i \{S_i + D_i\}$. As another example, if we have a cost associated to each variable–value assignment and we have to minimize the overall cost, in the model we introduce a domain variable C_i representing the cost of the assignment of each problem variable. The objective function is $Z = \sum_i C_i$.

Constraint Programming Solving

The CP solution process interleaves constraint propagation and tree search. The search process enumerates all possible variable–value assignments, until we find a solution or we prove that none exists. To reduce the exponential number of variable–value pairs in the search tree,

domain filtering and constraint propagation are applied at each node of the search tree. Domain filtering operates on individual constraints and removes provably inconsistent domain values. Since variables are involved in several constraints, domain updates are propagated to the other constraints whose filtering algorithms are triggered and possibly remove other domain values.

Filtering algorithms for being effective should be efficient and incremental as they are applied at each node of the search tree. Also they should try to remove as many inconsistent values as possible. If they remove all inconsistent values w.r.t. a constraint C , C is made *domain consistent*. Domain consistency is also called *hyper-arc consistency* or *generalized arc consistency*. However, checking all variable–value pairs for consistency could be extremely computationally expensive.

For this reason, symbolic constraints in general embed propagation algorithms which exploit the semantics of the constraint itself [13,18,19]. Consider, for example, the symbolic constraint *alldifferent* ($[X_1, \dots, X_n]$). It declaratively holds if all variables are assigned to a different value and it is equivalent to a set of binary inequality constraints connecting each pair of values in the list $[X_1, \dots, X_n]$. However, we can perform more global and informed reasoning on the set of variables. In Ref. 13, a filtering algorithm based on graph matching has been defined achieving hyper-arc consistency. It builds a bipartite graph whose nodes are divided into two sets: variable nodes and value nodes. There is an arc between a variable X and a value node v if $v \in D(X)$. The algorithm removes values that do not belong to any feasible matching that covers all variable nodes. We here provide an intuitive example on how the algorithm prunes the search space by reasoning globally. Suppose for example that we have an *alldifferent* constraint among three variables $[X_1, X_2, X_3]$ whose domains are $D(X_1) = D(X_2) = [1, 2]$ and $D(X_3) = [1 \dots 10]$. While a set of binary inequality constraints cannot infer any value removal, the *alldifferent* constraint can reason globally on the cardinality of the sets of variables and values. We have two variables, that is, X_1 and X_2 , whose common domains

$D(X_1) = D(X_2) = [1, 2]$ contain exactly two values. Thus, values 1 and 2 are *reserved* for variables X_1 and X_2 (no matter which value is assigned to which variable), and are no longer feasible for variable X_3 whose domain is reduced to $[3...10]$.

At the end of the constraint propagation process, we have three possible scenarios: (i) a domain becomes empty and a failure occurs; (ii) a solution is found, that is, all variables are assigned to one value; (iii) some domains contain more than one value. In this third case, since constraint propagation is not complete, we need a search strategy in order to explore the remaining search tree.

The way the search space is explored greatly influences the performances of the overall constraint solving process. An important point to be clarified is that during the search, constraints are always taken into account and propagated in order to prune, as much as possible, the search space. In fact, a variable instantiation triggers all the filtering algorithms of the constraints involving that variable and a propagation process starts again. All CP languages have high level predicates enabling the definition of search heuristics (branching methods). This leads to the development, within the CP community of sophisticated branching methods for many type of problems allowing to solve them effectively.

Optimization

In some applications we are not looking for a feasible solution, but for an optimal one w.r.t. some objective function f defined on problem variables. With no loss of generality, we restrict our discussion to minimization problems. CP systems usually implement a naive form of Branch and Bound algorithm to find an optimal solution. The idea is to solve a set of decision (feasibility) problems (i.e., a feasible solution is found if it exists), leading to successively better solutions. In particular, each time a feasible solution z^* is found (whose associated cost is $f(z^*)$), a constraint $f(x) < f(z^*)$, where x is any feasible solution, is added to each subproblem in the remaining search tree. The purpose of the added constraint, called *upper bounding constraint*, is to remove portions of the search

space which cannot lead to better solutions than the best one found so far. The problem with this approach is twofold: (i) CP does not rely on sophisticated algorithms for computing lower and upper bounds for the objective function, but derives their values starting from the variable domains; (ii) in general, the link between the objective function and the problem decision variables is quite poor and does not produce effective domain filtering.

Therefore, recently some efforts have been performed in order to embed in CP some techniques that take into account some form of *optimality reasoning*. In the rest of this article, we will focus on the description of the integration of MP techniques into CP.

INTEGRATION THROUGH GLOBAL CONSTRAINTS

One of the most important aspects of CP languages is the extensive use of global constraints. Global constraints, also called *symbolic constraints*, are n -ary constraints that represent suitable abstractions embedding sophisticated, semantic-aware filtering algorithms.

Global constraints are a very effective mean for integration [20]. The reason is twofold: first, global constraints represent structured subproblems for which efficient algorithms can be devised; second, the reasoning performed by global constraints is local; therefore, they can be developed as independent components interacting through propagation.

MP-Based Filtering

Some constraints represent a polynomial problem. In this case, hyper-arc consistency can be achieved in polynomial time with a special purpose algorithm. For example, one of the most widely used and successful global constraints is the *alldifferent* constraint: it is defined on a set of variables $[X_1, \dots, X_n]$ ranging on domains $[D(X_1), \dots, D(X_n)]$ and it holds if and only if all variables are assigned to different values. The linear model of the constraint can be obtained via a mapping between CP and integer programming variables, first suggested by Rodosek *et al.*

Figure 1. The *alldifferent* constraint filtering.

[21]. We have a set of decision variables x_{ij} that take the value 1 if the CP variable X_i is assigned to value j , 0 otherwise. Since each CP variable can be assigned to a single value in its domain, we have the constraints

$$\sum_j x_{ij} \leq 1 \quad \forall i.$$

Since all variables should assume different values, we have

$$\sum_i x_{ij} = 1 \quad \forall j.$$

The integrality constraint is part of this model. However, the coefficient matrix is totally unimodular meaning that linear programming provides an integer solution. Clearly, the addition of side constraints would break this structure. However, the *alldifferent* constraint is treated locally in CP, thus exploiting the unimodularity property. For this reason the *alldifferent* constraint embeds a polynomial-time filtering algorithm achieving domain consistency.

Many global constraints exploit graph theory results and algorithms for pruning inconsistent values. The filtering algorithm for the *alldifferent* constraint achieves hyper-arc consistency [13] by applying a maximum matching algorithm on a bipartite graph $G = (X \cup V, E)$, called *value graph* [22] built as follows: X is a set of nodes representing variables involved in the constraint, V is a set of nodes representing values contained in the union of the domains, and E represents the set of edges, $(X_i, v) \in E$ if and only if $v \in D(X_i)$. Hyper-arc consistency of an *alldifferent* constraint is established by computing a maximum matching M which covers X and identifying all edges that belong to a maximum matching. Consider for example five variables with the corresponding domain $W ::$

$[b, c, e]$, $X :: [b, c, d]$, $Y :: [e, d]$, $Z :: [e, d]$, and $K :: [a, b, c, e]$. The value graph is depicted in the left side of Fig. 1. The filtering algorithm removes all values that do not belong to a matching covering the set of variables leading to the deletion represented in the right part of Fig. 1. The complexity of computing a maximum matching (or prove there is none) is $O(m\sqrt{n})$ where m is the number of edges and n the number of variables. The complexity of finding all edges belonging to a maximum matching and thus also achieving hyper-arc consistency can be done in $O(m)$ [23].

Another constraint exploiting graph theory algorithms for achieving hyper-arc consistency is a generalization of the *alldifferent* constraint: the global cardinality constraint, *gcc*. The *gcc* [17] limits the cardinality of each value assumed by a set of variables.

Consider the example taken from Ref. 17 where we have seven variables representing employees (peter, paul, mary, john, bob, mike, and julia) and five values representing shifts. We know that for the shifts M and D we need at least one and at most two people, for shift N exactly one person is required and for shifts B and O we need at least zero and at most two people. The syntax of the constraint is the following:

$gcc([peter, paul, mary, john, bob, mike, julia],$
 $[M, D, N, B, O], [1, 1, 1, 0, 0], [2, 2, 1, 2, 2]).$

The value graph of this constraint is depicted in the leftmost part of Fig. 2. Intuitively, the filtering algorithm reasons as follows. Variables peter, paul, mary, and john have only two domain values in their domains, namely, M and D. These four variables should be assigned, no matter how, to these values. Since the sum of the upper bound values for these two values is 4, they are not available for any other variable.

Figure 2. The gcc constraint filtering.

Therefore, they are deleted from the domain of bob and mike. After this deletion bob has a single value in its domain, namely, N whose upper bound is 1. Therefore, it is no longer available for variables mike and julia. The filtered domains are depicted on the rightmost side of Fig. 2.

Again, graph theory is used for achieving hyper-arc consistency and for pruning all infeasible values. Let us start with the value graph (bipartite graph) presented for the *alldifferent* constraint. We have two sets of nodes: variable nodes and value nodes. Here we add a source node s and a sink node t . In addition arcs are associated with a demand and a capacity and are divided in three sets:

- those starting from s and ending in a value node. Their demand is $l(v)$ and their capacity is $u(v)$;
- those connecting a value and a variable node (that are the same for the *alldifferent* constraint). Their demand is 0 and their capacity is 1;
- those starting from a variable node and ending in t . Their demand is 0 and their capacity is 1.

The graph for the above example is depicted in Fig. 3.

A solution of *gcc* corresponds to a maximum flow of value n from s to t in the above

mentioned graph, where n is the number of variables involved. An arc connecting variable x_i with value v can be part of a solution if it carries positive flow in the maximum flow solution, or it carries zero flow but has a reduced cost of zero. Reduced costs can be rapidly computed for identifying strongly connected components of the residual graph. The maximum flow can be found in $O(nm)$, where m is the number of edges in the graph. Again hyper-arc consistency can be achieved in $O(m + n)$. In addition, flow algorithms are incremental and each time a value is removed from a domain of a variable, the filtering algorithm should not start from scratch. Another more complex example of filtering algorithm based on flow for the sequence constraint can be found in Ref. 24.

Beside graph theory, dynamic programming has also been embedded into global constraints. It has been used for the knapsack constraint, or subset-sum constraint [25].

Beldiceanu's *global constraints catalogue* [26] lists some 350 constraints which are explicitly described in terms of graph properties and/or automata.

MP-Based Filtering on Costs. Graph-based algorithms can be also used to implement the so called *cost-based filtering*. Let us consider again an *alldifferent* constraint but now variables have an associated cost. The resulting constraint is called *minweightalldiff*

Figure 3. The gcc graph for computing the maximum flow.

[27]. Let $X_1, \dots, X_n$, be the problem decision variables and be Z the cost variable. Let $D(X_1), \dots, D(X_n)$ be the domains associated to variables X and $D(Z)$ the domain of Z . We have either to minimize the cost variable during the solution process or we have an upper bound on it (corresponding to the domain upper bound $D_{\max}(Z)$). Now let w_{ij} for $i = 1, \dots, n$ and all $j \in \bigcup D(X_i)$ be constants representing costs/weights. Then *minweightalldiff*($X_1, \dots, X_n, Z, w$) holds if and only if $X_i \neq X_k$ for all $i, k \in 1, \dots, n$ and $\sum_{i, X_i=j} w_{ij} \leq Z$.

This constraint has a linear formulation equal to the *alldifferent* with in addition the following objective function:

$$\min \sum_i \sum_j x_{ij} w_{ij}.$$

The coefficient matrix is again totally unimodular. Therefore, the problem is polynomial. For this reason achieving hyper-arc consistency is doable and the algorithm is again based on graph theory, and specifically on the minimum cost flow. The graph has the same structure as the one built for the *gcc*. We have variable nodes, value nodes, a source s , and a sink t . Each arc has an associated capacity equal to 1 and a cost. The cost is 0 for those arcs that start from the source and end in variable nodes and for those arcs that start from value nodes and end in the sink. The cost is instead c_{ij} on those arcs that start from variable nodes and end in value nodes. The constraint is consistent if

- a feasible flow f from s to t exists, its value is n corresponding to the number of variables and $\text{cost}(f) \leq D_{\max}(Z)$; and
- the minimum cost $s - t$ flow f has a value n and $\text{cost}(f) \geq D_{\min}(Z)$.

In the same way, also for the global cardinality constraints with costs a polynomial-time algorithm based on minimum cost flow [19] has been proposed for achieving hyper-arc consistency.

Similarly to constraints reasoning on optimization, recently soft-global constraints have been developed exploiting the same techniques, but considering the cost of the

violation to be minimized, see Ref. 28 for a survey.

Non-polynomial Structures

Hyper-arc consistency can be achieved in polynomial time only if the constraint represents a polynomial problem. In some cases, global constraints represent NP-hard problems. Therefore, the constraint embeds a filtering algorithm that enforces a weaker notion of consistency w.r.t. hyper-arc consistency.

As an example, let us consider the cumulative constraint widely used in scheduling problems whose parameters are: a list of variables $[S_1, \dots, S_n]$ representing the starting time of all activities sharing the resource, their duration $[D_1, \dots, D_n]$, the resource consumption for each activity $[R_1, \dots, R_n]$, and the available resource capacity C

$$\text{cumulative}([S_1, \dots, S_n], [D_1, \dots, D_n], [R_1, \dots, R_n], C).$$

Many filtering algorithms have been implemented for this constraint, none achieving hyper-arc consistency of course [29]. A successful algorithm, introduced by the OR community is the edge finder [30], and embedded as filtering algorithm in CP global constraints by Baptiste *et al.* [31].

An example is depicted in Fig. 4 where three activities S1, S2, and S3 must be scheduled on a single capacity machine. Their duration is respectively, 6, 4, and 3, their earliest start times are respectively, 0, 1, and 1 and their latest completion times are respectively, 17, 11, and 12. If activity S1 starts as soon as possible, before S2 and S3, its earliest completion time is 6. The sum of the durations of S2 and S3 is 7 while the difference between the maximum latest completion time of S2 and S3 and the earliest completion time of S1 is 6. Therefore, we can conclude that both S2 and S3 should precede S1, whose earliest start time becomes 8.

The edge finder has been extended to cope with non unary resources. Also variants of the cumulative constraint for preemptive activities, for unary and cumulative resources are presented in Ref. 29.

Figure 4. Edge finder.

Constraint-Specific Relaxations

When the constraint represents an NP-hard problem, variables have an associated cost and Z is the cost variable on which we have an upper bound, only an approximation of hyper-arc consistency can be achieved. Therefore, a possibility is to embed in the constraint a relaxation of the constraint itself as proposed in Ref. 32.

Whatever relaxation is used, the unique requirement concerns its output. The relaxation should return three results as follows:

- the optimal solution of the relaxed problem x^* ;
- the optimal solution objective function value LB . This value represents a lower bound the cost variable Z ;
- a gradient function $grad(X_i, j)$ measuring the variable–value assignment cost.

These pieces of information are exploited by the CP solver not only for filtering purposes, but also for guiding the search toward promising branches (in terms of costs), see the section titled “Search and Optimization.”

An example of the use of these pieces of information is the following: we use the traditional mapping between the CP variables involved in the constraints and those involved in the relaxation. We have a binary variable x_{ij} corresponding to each variable–values pair in CP. In particular, $x_{ij} = 1$ if $X_i = j$ in CP, while $x_{ij} = 0$ if $X_i \neq j$ in CP. Constraints $\sum_{j \in D(X_i)} x_{ij} = 1 \forall i$ are part of the mapping and impose that exactly one value should be assigned to each CP variable.

In addition, if a variable–value assignment in CP has a cost, then the obvious link between the cost variable of the CP model Z and the lower bound value LB computed by solving the relaxation is $LB \leq Z$. If LB is greater or equal than the upper bound of the

domain of Z , a failure occurs since the domain of Z becomes empty.

Given this mapping, the variable x_{ij} in the relaxation corresponds to the value j in the domain of the CP variable X_i . Thus, reduced costs $\bar{c}_{ij}$ provide an optimistic evaluation on the cost of CP variable domain values, $grad(X_i, j) = \bar{c}_{ij}$. More formally, for each domain value j of each variable X_i , we can compute a lower bound on the subproblem generated if value j is assigned to X_i as

$$LB_{X_i=j} = LB + grad(X_i, j).$$

If $LB_{X_i=j}$ is greater or equal to the upper bound of the domain of Z , j can be deleted from the domain of X_i .

This filtering algorithm performs a real back-propagation from Z to X_i . Such a technique is known in MP as *variable fixing*. However, variable fixing in the MP context does not trigger in general an iterative process. On the contrary, in CP, filtering variable domains triggers constraints imposed on the modified variables.

An important point which should be stressed is that this filtering algorithm is general and can be applied whenever the relaxation is able to provide these pieces of information. The filtering algorithm is independent on the structure of the relaxation.

SEARCH AND OPTIMIZATION

CP search is similar to MP branch and bound. In fact, it explores a search tree whose leaves are either solutions or inconsistent nodes. In a MP search tree, each node has at most two descendants, but in a CP search tree a node may have many descendants. This is a key difference between CP and MP search.

Second, in a MP search tree a child of a node differs from its parent just in one

(tighter) bound on one variable. In a CP search tree the child typically has one variable instantiated to a fixed value. This form of search is called *labeling*. Nevertheless, other forms of CP search may be used instead of labeling, as any arbitrary constraint can be imposed at each branch. For example, in a scheduling application the added constraint may enforce that one task cannot be scheduled until another has finished.

In general a search tree in CP is explored in depth first, with some notable variants. Credit search [33] is an incomplete method where the number of nondeterministic choices is limited a priori. Another widely used search strategy is the limited discrepancy search (LDS). LDS was first introduced by Harvey and Ginsberg [34]. The idea is that if the heuristic is accurate, it will make the wrong decision only few times. Note that the term *heuristic* has a different meaning w.r.t. the one used in OR. Technically, a heuristic is a function that takes a state as input and outputs a value for that state, often as a guess of how far away that state is from the solution. Thus, at each node of the search tree, the heuristic is supposed to provide the *good* choice (corresponding to the leftmost branch) among possible alternative branches. Any other choice would be *bad* and is called a *discrepancy*. In LDS, one tries to find first the solution with as few discrepancies as possible. LDS builds a search tree in the following way: the first solution explored is that suggested by the heuristic. Then solutions that follow the heuristic for every variable but one are explored: these solutions are that of discrepancy equal to one. Then, solutions at discrepancy equal to two are explored, and so on.

A variant of LDS for dealing with objective functions proposed in the OR community is local branching [35]. The idea is to explore a given discrepancy around a reference solution (neighborhood) and change reference solution if case a better one is encountered in the neighborhood. Discrepancy constraints, also called *local branching constraints* are linear inequalities used to model the neighborhood and to improve its bound. Local branching has been implemented and

properly extended to be smoothly integrated into the CP machinery in Ref. 36.

Branching Heuristics

During search, two fundamental choices highly influence the efficiency of the solution process in CP: (i) the selection of the variable to instantiate, that is, the *variable selection heuristics* and (ii) the selection of the value to assign, that is, the *value selection heuristics*.

These heuristics can be either problem independent or problem specific. An example of problem independent variable selection heuristics is first fail, assigning first the variables that has the smallest domain, as it is the most difficult variable to instantiate. Another recent and successful general purpose search strategy for CP is based on the concept of the impact of a variable [37]. The impact measures the importance of a variable for the reduction of the search space. Impacts are learnt during search. If combined with restart, impact based search outperforms almost all general purpose heuristics.

On the other hand problem dependent heuristics can be designed. An example is the following: in scheduling problems if we have to minimize the makespan a good choice is to select first the task with the smallest earliest start time.

Although we have distinguished variable and value ordering heuristics, there is an important class of heuristics that address variable and value orderings simultaneously. These are relaxation heuristics, which are based on the solution of a relaxed problem at each node of the search tree. If the (optimal) solution to the subproblem is also a feasible solution for the original problem, we have reached a leaf node of the search tree. If, on the other hand, some of the original problem constraints are violated, we choose a variable assignment that conflicts with the constraint. We then assign a different value to the variable in order to satisfy the constraint. A notable example of relaxation based heuristic is the one performed by MP branch and bound. Moreover the constraints omitted from the relaxed problem can be used actively to guide the search heuristics. In CP an example of search heuristic to handle the

relaxed constraint violation is called *unimodular probing* [38].

Using (Linear) Relaxations during Search

The use of MP techniques in CP has shown to be very effective in practice not only when the relaxation is embedded within a CP global constraint, but also when a linear solver is used as a global constraint and triggered at each node of the CP search tree as happens in MP branch and bound. These techniques were proposed first in Ref. 39 and extended by Refalo [40].

For this purpose the problem model should be stated in the CP solver and also passed to the linear programming solver via a mapping. For being effective the interaction between the two solvers should last during the overall computation. Therefore, a communication link between the CP constraints and the linear solver should be established. For this purpose, quite often the linear solver is considered as a software component similar to other constraints, interacting with them and exchanging information. Three pieces of information should be passed back and forth: variable fixing, bound reduction, and the optimal solution of the relaxation. Each time the CP propagation infers a new bound, it should be passed as a linear constraint to the linear solver which takes it into account in next recomputations. Also, variable fixing from the LP solver are passed to the CP solver as traditional propagations. The solution of the relaxation, that is, the lower bound can be used as described in the section titled “Constraint-Specific Relaxations.”

Clearly this procedure is more effective if the bound is tight. Therefore, [40] proposed to tighten the relaxation with cutting planes added during search and coming from CP global constraints. Cutting planes can be derived from global constraints representing subproblems and added to the linear programming model so as to tighten the overall relaxation. It is interesting to note that cutting planes can be derived after domain reduction from the CP side, so as to maintain the tightness of the relaxation during the whole solution process. Refalo [40] provided many examples and shown that it is very effective in practice.

The two approaches, CP and LP, not only complement each other, but also support each other. The linear relaxation yields a bound on the cost variable, which enables additional propagation to occur. Propagation, conversely, tightens variable bounds which in turn tighten the linear relaxation. This again yields a tighter bound on the cost variable which enables more propagation and so on.

Other relaxations have been integrated into a CP solver. Lagrangian Relaxation is a very important example [41–43].

In addition, the CP literature reports some other attempts of dealing with the objective function during search. One possibility is to exploit cost based information coming from global constraints and use the solution of the relaxation to guide search, as shown in the section titled “Constraint-Specific Relaxations.” Examples of research efforts in this direction are Refs 32 and 44. Also, additive bounding has been used for tightening the bound and taking into account the structure of the search tree into the constraints [36,45].

DECOMPOSITION

An alternative way to explore the search space is to decompose the problem at hand into multiple subproblems and use the solver which is most suited for each part. Clearly the solvers should interact and exchange information. Two notable examples of decomposition are the logic-based Benders decomposition and the CP based column generation.

Logic-Based Benders Decomposition

Benders decomposition [46] has been studied in the 1960s and is an effective method for solving a variety of structured problems. It is particularly suited for those problems where fixing a number of *hard* variables makes the problem simpler. Instead of blindly trying tentative values for the *hard* variables we can solve a master problem (which takes into account constraints on *hard* variables). After fixing *hard* variables, a subproblem can be solved, taking into account the remaining variables. The process iterates and converges to the optimal solution. The iteration between the master and the subproblem is regulated

by the so called *Benders cuts*. In OR, the subproblem should be a linear program. Hooker and Ottosson [47] propose to remove this restriction, defining the logic-based Benders decomposition framework. In this setting, the subproblem can be expressed as a constraint satisfaction problem.

An interesting and successful application of logic-based Benders decomposition is scheduling with alternative resources, where each activity can run on a set of parallel machines of different speeds and costs. As an example, taken from Ref. 47, let us consider a scheduling problem where we want to minimize the cost of the schedule. Allocation is modeled and solved with integer linear programming, while the scheduling part is solved through CP. In this case, a set of single machine scheduling problems is solved while in other articles, for example, in Benini *et al.* [48], the scheduling problem is considered overall. Also, other examples with different objective functions are presented in Refs 49–51.

Column Generation

Column generation is a very different technique for improving on non-optimal solutions. It is a very useful approach for problems for which an integer-linear model would involve too many variables—in some cases the number of variables grows exponentially with the size of the problem. The purpose is to enable an optimal solution to be found, and proven optimal, without ever considering more than a small proportion of these variables—certainly only a number that grows polynomially with the problem size.

The CP environment can encapsulate column generation so that it is possible just to plug in the master problem constraints and the subproblem algorithm.

The functionality is similar to that offered by column generation libraries and packages such as Abacus [52] and BC-Opt [53].

Column generation in combination with CP was first introduced in Ref. 54 and has been used for a range of applications including time-tabling, crew scheduling, vehicle routing [55–58].

All these optimization problems may be decomposed in a natural way: they may be viewed as selecting a subset of individual patterns within a huge pool of possible and weighted patterns. The selected combination is the one with the lowest cost to fulfill some given global requirements. In the CP-based column generation framework the master subproblem is solved by traditional MP techniques, while the pricing subproblem is solved by CP. The main benefits of using CP are the expressiveness of its modeling language and the flexibility of its solvers for dealing with complex side constraints.

TOOLS ENABLING INTEGRATION

Many tools have been developed in the CP community that enable or support the integration of CP with integer programming techniques. Clearly, for space limitations it is not possible to be exhaustive in this article, but we list the main tools and their main features. For a survey, see Ref. 59.

ECLⁱPS^e [15] is a Prolog-based system whose aim is to serve as a platform for integrating Logic Programming extensions, the most important being constraint logic programming. ECLⁱPS^e enables to use different constraint solvers in combination: for instance they can share variables and/or constraints. The *eplex* library gives access to linear programming and mixed integer programming solvers, while the *ic* library implements the finite domain constraint solver. Column generation, Benders decomposition, and local search can be implemented in ECLⁱPS^e.

G12 [60] is a solver platform for solving large scale combinatorial problems. Three languages represent the core design of the platform: Zinc, Cadmium, and Mercury. Zinc is a modeling language that is independent from the underlying solver. Cadmium enables the mapping between Zinc models and the underlying solvers. Finally Mercury is a language for building extensible and hybridizable solvers.

OPL Development Studio is designed to support ILOG Cplex and ILOG CP Optimizer. OPL (Optimization Programming Language)

[61] allows to develop single models in either technology. In addition, OPL develops models that use either or both technologies. In addition CP Optimizer provides a new scheduling language together with an automatic, robust and efficient solution strategy, easily accessible to mathematic programmers.

On the other way round, in the Integer Programming community, a number of solvers have integrated CP concepts, like BARON [62], SIMPL [11], and SCIP [63].

CONCLUSION

The emerging research field of the integration of OR techniques in CP is extremely promising and motivating since there are many open issues and challenges to be addressed and studied. The first challenge concerns the user support for the problem solving process. The aim is to provide the user with an abstract conceptual model and let the solver choose the best algorithm to solve it. This is too simple and unrealistic of course, but as a first step, research in this direction should be done in the identification of a mapping between problem structures and a corresponding efficient algorithm.

A second challenge concerns the solution of problems whose data are partially unknown or ill-defined. The problem solving process here should focus not only on searching for the optimal solution, which is often meaningless, but also on its robustness to the unknown parameter changing and to external events. If the problem is defined on probabilistic data, stochastic optimization should be taken into account. For this purpose, many approaches have been studied in the field of OR. The CP community has recently faced stochastic problems: in Ref. 64 stochastic CP is introduced formally and the concept of solution is replaced with the one of *policy*. This work has been extended in Ref. 65 where an algorithm based on the concept of scenarios is proposed.

A third challenge concerns over-constrained problems, that is, those problems that have no solution. These problems are quite common in an industrial setting where solutions represent compromises and violate

some problem constraints. At the state of the art some approaches have been devised to face these problems: (i) rank constraints into classes of importance, (ii) add a penalty to constraints, and (iii) count the violation.

A fourth challenge concerns the improvement of each aspect of the CP solving process: propagation could be improved to cope with constraints representing NP-hard problems, while tree search is more and more often combined with local search and metaheuristics.

CONSTRAINT QUALIFICATIONS

MIKHAIL V. SOLODOV

 Castorina, Rio de Janeiro,
 Brazil, South America

Roughly speaking, (first-order) constraint qualifications (CQs) are properties of the analytical description of a set which ensure that the structure of the set around a given feasible point can be constructively captured by (first-order) approximations of the constraint functions defining the set. If it is so, the consequences are far reaching. CQs are essential for deriving primal and primal-dual characterizations of solutions of optimization and variational problems, duality relations, sensitivity and stability analysis, and convergence and rate of convergence of computational methods for solving optimization and variational problems.

Let D be any set in $\mathbf{R}^n$. An appropriate object to describe the geometry of D around a feasible point $\bar{x} \in D$ is the *tangent (or contingent) cone*

$$\mathcal{T}_D(\bar{x}) = \left\{ d \in \mathbf{R}^n \mid \begin{array}{l} \exists \{t_k\} \subset \mathbf{R}_+ \setminus \{0\}, \{t_k\} \rightarrow 0, \\ \exists \{d^k\} \subset \mathbf{R}^n, \{d^k\} \rightarrow d, \\ \text{such that } \bar{x} + t_k d^k \in D \\ \text{for all } k \end{array} \right\}.$$

The tangent cone includes all the feasible directions, if there are any, as well as “almost-feasible” ones in the stated sense. Suppose further that D is defined by a finite number of equality and inequality constraints, as is common in applications:

$$D = \{x \in \mathbf{R}^n \mid h(x) = 0, g(x) \leq 0\}, \quad (1)$$

where $h: \mathbf{R}^n \rightarrow \mathbf{R}^l$ and $g: \mathbf{R}^n \rightarrow \mathbf{R}^m$ are given functions, which we assume to be continuously differentiable in the region of interest. Then CQs can be thought of as conditions imposed on the functions h , g , and/or their derivatives at or around the

point $\bar{x}$, that guarantee that the tangent cone $\mathcal{T}_D(\bar{x})$ has an explicit algebraic representation in terms of the derivatives of the constraint functions. This is crucial for developing optimality conditions in optimization, since whenever a point $\bar{x}$ is a local solution of the problem

$$\text{minimize } f(x) \quad \text{subject to } x \in D, \quad (2)$$

where $f: \mathbf{R}^n \rightarrow \mathbf{R}$ is differentiable at $\bar{x}$, it holds that

$$\langle f'(\bar{x}), x - \bar{x} \rangle \geq 0 \quad \forall x \in \bar{x} + \mathcal{T}_D(\bar{x}). \quad (3)$$

Or equivalently,

$$-f'(\bar{x}) \in (\mathcal{T}_D(\bar{x}))^\circ, \quad (4)$$

where $K^\circ = \{z \in \mathbf{R}^n \mid \langle z, y \rangle \leq 0 \forall y \in K\}$ stands for the dual (negative polar) cone of a cone K in $\mathbf{R}^n$. Constraint qualifications allow explicit characterization of the tangent cone in condition (3) and of its dual in condition (4), which makes these abstract optimality conditions tractable.

For the same reasons, CQs are important for solving the more general variational problems of the form

$$\begin{aligned} &\text{find } \bar{x} \in D \text{ such that } \langle F(\bar{x}), x - \bar{x} \rangle \geq 0 \\ &\forall x \in \bar{x} + \mathcal{T}_D(\bar{x}), \end{aligned} \quad (5)$$

or equivalently,

$$-F(\bar{x}) \in (\mathcal{T}_D(\bar{x}))^\circ, \quad (6)$$

where $F: \mathbf{R}^n \rightarrow \mathbf{R}^n$. When for some function $f: \mathbf{R}^n \rightarrow \mathbf{R}$, it holds that $F(x) = f'(x)$, $x \in \mathbf{R}^n$, then problem (5) represents the primal optimality conditions for the optimization problem (2), while condition (6) leads to the primal-dual optimality conditions. But in the variational setting F need not be integrable in general. When the feasible set D is convex, problem (5) becomes equivalent to

the classical *variational inequality*

$$\begin{aligned} &\text{find } \bar{x} \in D \text{ such that } \langle F(\bar{x}), x - \bar{x} \rangle \geq 0 \\ &\forall x \in D. \end{aligned}$$

Derivation of tractable first-order primal and primal-dual necessary optimality conditions via computing the tangent cone in condition (3) and its dual in condition (4) is perhaps the most important role of constraint qualifications. The term *CQ* was coined in Ref. 1. Alternatively, the term *regularity* is also sometimes used in the literature to refer to (some of the) CQs. CQs also appear in second-order necessary optimality conditions. And, as already mentioned, they play an important role in deriving duality relations, sensitivity/stability analysis, error bound estimates, and convergence and rate of convergence of computational methods.

TANGENT CONE AND FIRST-ORDER PRIMAL-DUAL OPTIMALITY CONDITIONS

Consider a set D defined by a finite number of equality and inequality constraints, as in Equation (1). Let $\bar{x} \in D$ be any feasible point. If $g_i(\bar{x}) < 0$ for some $i \in \{1, \dots, m\}$, by continuity $g_i(x) < 0$ for all $x \in \mathbf{R}^n$ close to $\bar{x}$, and it is clear that such constraints (*inactive* at $\bar{x}$) do not influence the geometry of the set D around the point $\bar{x}$. Let

$$A(\bar{x}) = \{i = 1, \dots, m \mid g_i(\bar{x}) = 0\},$$

be the set of inequality constraints *active* at $\bar{x}$. All the equality constraints are, of course, active at any feasible point. Consider now the cone of directions obtained by linearizing all the constraints active at $\bar{x}$:

$$\begin{aligned} \mathcal{L}_D(\bar{x}) &= \{d \in \mathbf{R}^n \mid h'(\bar{x})d = 0, \\ &\quad \langle g'_i(\bar{x}), d \rangle \leq 0 \quad \forall i \in A(\bar{x})\}, \end{aligned}$$

which is an intuitively natural candidate to represent directions tangent to D at the point $\bar{x}$. It is easy to see that $\mathcal{T}_D(\bar{x}) \subset \mathcal{L}_D(\bar{x})$ always. The fundamental question is when in fact it holds that

$$\mathcal{T}_D(\bar{x}) = \mathcal{L}_D(\bar{x}). \quad (7)$$

When the latter is the case, applying a theorem of the alternatives [2] to compute the dual of $\mathcal{L}_D(\bar{x})$, we have that

$$\begin{aligned} (\mathcal{T}_D(\bar{x}))^\circ &= \{z \in \mathbf{R}^n \mid z = \sum_{i=1}^l \lambda_i h'_i(\bar{x}) + \sum_{i \in A(\bar{x})} \mu_i g'_i(\bar{x}), \\ &\quad \lambda \in \mathbf{R}^l, \mu_i \geq 0 \quad \forall i \in A(\bar{x})\}. \end{aligned} \quad (8)$$

Then the characterization (6) of solutions of the variational problem (5) immediately translates into the following: there exists $(\lambda, \mu) \in \mathbf{R}^l \times \mathbf{R}^m$ such that

$$\begin{aligned} -F(\bar{x}) &= \sum_{i=1}^l \lambda_i h'_i(\bar{x}) + \sum_{i=1}^m \mu_i g'_i(\bar{x}), \\ h(\bar{x}) &= 0, \\ g(\bar{x}) &\leq 0, \quad \mu \geq 0, \quad \mu_i = 0 \quad \forall i \notin A(\bar{x}). \end{aligned} \quad (9)$$

In the case of $F(x) = f'(x)$, $x \in \mathbf{R}^n$, corresponding to the optimization problem, relations (9) are the *Karush–Kuhn–Tucker optimality (KKT) conditions*

$$\begin{aligned} \frac{\partial L}{\partial x}(\bar{x}, \lambda, \mu) &= 0, \\ h(\bar{x}) &= 0, \\ g(\bar{x}) &\leq 0, \quad \mu \geq 0, \quad \mu_i = 0 \quad \forall i \notin A(\bar{x}), \end{aligned} \quad (10)$$

where

$$\begin{aligned} L &: \mathbf{R}^n \times \mathbf{R}^l \times \mathbf{R}^m \rightarrow \mathbf{R}, \\ L(x, \lambda, \mu) &= f(x) + \langle \lambda, h(x) \rangle + \langle \mu, g(x) \rangle \end{aligned}$$

is the Lagrangian of the problem.

The key question, therefore, is when equality (7) or more generally equality (8) are guaranteed to hold. Obviously, equality (7) is sufficient for equality (8) but not necessary. Equality (7) is called *Abadie CQ* [3], and equality (8) is called *Guignard CQ* [4]. Guignard CQ is in a sense the weakest CQ that ensures that KKT relations (10) are necessary optimality conditions for the associated optimization problem [5]. It should be emphasized though that neither Abadie CQ nor Guignard CQ is verifiable directly in general, since they require the knowledge of the tangent cone or its dual. They are more akin to the desired properties we would like to ensure than CQs as such.

Before proceeding with the presentation of CQs, we make one final observation. CQs and the desired equality (7) depend not only on the geometry of the set D , but also on its analytic representation, that is, on the choice of the constraint functions h and g in Equation (1). For example, consider the set $D = \{0\}$ that has the unique feasible point $\bar{x} = 0$, so that $\mathcal{T}_D(\bar{x}) = \{0\}$. If this set is represented by the equality constraint with $h(x) = x$, then in Equation (1), we get $\mathcal{L}_D(\bar{x}) = \{0\}$ which gives the correct tangent cone, that is, equality (7) holds. If, on the other hand, the set is represented by the equality constraint with $h(x) = \|x\|^2$, then in Equation (1), we get $\mathcal{L}_D(\bar{x}) = \mathbf{R}^n$ and (7) is no longer valid.

Probably the most obvious CQ that guarantees equality (7) is *linearity* of constraints around the point in question. Specifically, if there exists a neighborhood U of $\bar{x}$ such that

$$h \text{ and } g_i \forall i \in A(\bar{x}) \text{ are affine in } U,$$

then equality (7) holds. Moreover, in that case the tangent cone is the set of feasible directions at $\bar{x}$.

The linear independence constraint qualification (LICQ) consists of saying that the gradients of equality and active inequality constraints are linearly independent at $\bar{x}$:

$$\begin{aligned} &\text{the set } \{h'_i(\bar{x}), i = 1, \dots, l\} \cup \{g'_i(\bar{x}), i \in A(\bar{x})\} \\ &\text{is linearly independent.} \end{aligned} \quad (11)$$

Apart from the characterization (7) of the tangent cone, LICQ further implies that the multiplier (λ, μ) satisfying primal-dual relations (9) is actually unique.

The *Mangasarian–Fromovitz constraint qualification* (MFCQ, [6]) assumes that

$$\begin{aligned} &\text{the set } \{h'_i(\bar{x}), i = 1, \dots, l\} \text{ is linearly} \\ &\text{independent and } \exists d \in \mathbf{R}^n \text{ such that} \\ &h'(\bar{x})d = 0, \langle g'_i(\bar{x}), d \rangle < 0 \forall i \in A(\bar{x}). \end{aligned} \quad (12)$$

Applying a theorem of the alternatives [2], the equivalent dual form of MFCQ states that

zero is the unique solution of

the linear system

$$\begin{aligned} &\sum_{i=1}^l \lambda_i h'_i(\bar{x}) + \sum_{i \in A(\bar{x})} \mu_i g'_i(\bar{x}) = 0, \\ &\mu_i \geq 0 \quad \forall i \in A(\bar{x}). \end{aligned} \quad (13)$$

MFCQ (12) also implies the characterization (7) of the tangent cone, while being evidently weaker than LICQ (11). Also, using the dual form (13), it is not difficult to see that at solutions of the variational problem (5), MFCQ is equivalent to the property of the multiplier set of (λ, μ) satisfying the primal-dual relations (9) being nonempty and bounded [7]. If $\bar{x}$ satisfies the primal-dual relations (9) with some (λ, μ) , then the stronger property of uniqueness of Lagrange multipliers is called the *strict Mangasarian–Fromovitz constraint qualification* (SMFCQ, [8]). MFCQ is stable in the following sense. If MFCQ holds at $\bar{x} \in D$ then there exists a neighborhood U of $\bar{x}$ such that MFCQ holds at each $x \in D \cap U$.

Slater constraint qualification consists of the following assumptions:

$$\begin{aligned} &h \text{ is an affine function, each } g_i \text{ is a} \\ &\text{convex function, and } \exists \hat{x} \in \mathbf{R}^n \text{ such that} \\ &h(\hat{x}) = 0, g_i(\hat{x}) < 0 \quad \forall i \in \{1, \dots, m\}. \end{aligned}$$

If g is convex differentiable and no equations appear, then Slater CQ is equivalent to MFCQ (12) holding at every point $\bar{x} \in D$ [9,10].

In the case when the description (1) of the set D does not contain inequality constraints LICQ, MFCQ, and SMFCQ all reduce to the classical *regularity* condition

$$\text{rank } h'(\bar{x}) = l.$$

The fact that under this assumption $\mathcal{T}_D(\bar{x})$ is the tangent subspace $\ker h'(\bar{x})$ is a consequence of the Lyusternik–Graves Theorem [11,12]; see also Ref. 13. Furthermore, KKT relations (10) for optimization reduce in this case to the classical Lagrange optimality conditions.

The *constant rank constraint qualification* (CRCQ, [14]) holds at $\bar{x} \in D$ if there exists a

neighborhood U of $\bar{x}$ such that

for every pair of index sets $I \subset \{1, \dots, l\}$
and $J \subset A(\bar{x})$ the set
 $\{h'_i(x), i \in I\} \cup \{g'_i(x), i \in J\}$
has the same rank for all $x \in D \cap U$.

(14)

In condition (14) the rank in question depends on the choice of I and J but not on the point $x \in D \cap U$. Clearly, LICQ (11) implies CRCQ (14). Linearity of constraints also implies CRCQ. Under CRCQ it holds that the tangent cone $\mathcal{T}_D(\bar{x})$ has the form (7) [14]. CRCQ is neither weaker nor stronger than MFCQ (12). Thus, nothing can be said about the multiplier set in KKT relations (9), except that it is nonempty. Note also that unlike MFCQ, if CRCQ holds at $\bar{x} \in D$, it will continue to hold if any of the equality constraints $h_i(x) = 0$ were to be replaced by the two inequalities $h_i(x) \leq 0$ and $-h_i(x) \leq 0$. MFCQ and CRCQ are related, however, in the following sense: it can be shown that under CRCQ, there exists an alternative representation of the feasible set for which MFCQ holds [15].

The *relaxed constant rank constraint qualification* (rCRCQ, [16]) holds at $\bar{x} \in D$ if there exists a neighborhood U of $\bar{x}$ such that

for every index set $J \subset A(\bar{x})$ the set
 $\{h'_i(x), i = 1, \dots, l\} \cup \{g'_i(x), i \in J\}$
has the same rank for all $x \in U$.

(15)

It is clear that CRCQ (14) implies rCRCQ (15). It can be seen from the following example [16] that the reverse implication is not valid: $D = \{x \in \mathbf{R}^2 \mid x_1 - x_2 = 0, -x_1 \leq 0, -x_1 - x_2^2 \leq 0\}$, $\bar{x} = 0$. It holds that rCRCQ is still sufficient for the tangent cone $\mathcal{T}_D(\bar{x})$ to have the desired form (7) [16]. When there are no inequality constraints, rCRCQ reduces to the *weak constant rank condition* introduced in Ref. 17.

The point $\bar{x} \in D$ satisfies the *constant positive linear dependence* condition (CPLD, [18]), if there exists a neighborhood U of $\bar{x}$ such

that

whenever for some index sets $I \subset \{1, \dots, l\}$
and $J \subset A(\bar{x})$ the system
 $\sum_{i \in I} \lambda_i h'_i(\bar{x}) + \sum_{i \in J} \mu_i g'_i(\bar{x}) = 0,$
 $\mu_i \geq 0 \forall i \in J$
has a nonzero solution, the set
 $\{h'_i(x), i \in I\} \cup \{g'_i(x), i \in J\}$
is linearly dependent for all $x \in U$.

(16)

Comparing the dual form (13) of MFCQ with condition (16), it is immediate that MFCQ implies CPLD but not vice versa. It can be seen that CPLD is also weaker than CRCQ [19]. Nevertheless, CPLD still guarantees that the tangent cone has the desired representation (7); this follows from the results in Refs 19, 20; and also from the error bound in Ref. 16, also see the section titled “Error Bounds and Metric Regularity.” Hence, KKT relations (10) are necessary optimality conditions, which had also been shown in Ref. 19. Finally, CPLD is neither weaker nor stronger than rCRCQ, as can be seen from the following example [16]: $D = \{x \in \mathbf{R}^2 \mid x_2 = 0, x_1 - x_2^2 \leq 0, -x_1 - x_2^2 \leq 0\}$, $\bar{x} = 0$.

The point $\bar{x} \in D$ is said to be *quasinormal* [20, 22] if

there exist no nonzero $(\lambda, \mu) \in \mathbf{R}^l \times \mathbf{R}_+^m$
and no sequence $\{x^k\} \rightarrow \bar{x}$ such that

$$\sum_{i=1}^l \lambda_i h'_i(\bar{x}) + \sum_{i=1}^m \mu_i g'_i(\bar{x}) = 0, \text{ and} \\ \text{for all } k, \lambda_i h'_i(x^k) > 0 \text{ for all } i \text{ with } \lambda_i \neq 0, \\ \mu_i g'_i(x^k) > 0 \text{ for all } i \text{ with } \mu_i \neq 0. \quad (17)$$

Quasinormality implies that the tangent cone has the desired representation (7) [21]. Quasinormality is implied by CPLD [19].

The main relationships discussed above can be summarized as follows:

When comparing different CQs, it should also be kept in mind that conditions like CPLD (16) and rCRCQ (15) depend not only on the properties of the problem data at the point $\bar{x}$ but also on their properties in some neighborhood of this point. They require more information and, unless some stronger sufficient conditions hold, they are usually much more difficult to verify directly than, say, the classical MFCQ (12).

The more general format of constraints is given by

$$D = \{x \in \mathbf{R}^n \mid S(x) \in Q\}, \quad (18)$$

where Q is a subset of $\mathbf{R}^s$ and $S : \mathbf{R}^n \rightarrow \mathbf{R}^s$. The set (1) defined by a finite number of equality and inequality constraints is clearly a special case of Equation (18) given by $s = l + m$, $S(x) = (h(x), g(x))$, and $Q = \{0\} \times (-\mathbf{R}_+^m)$. When Q is a closed convex set, the Robinson CQ [10] holds at $\bar{x} \in D$ if

$$0 \in \text{int} \{S(\bar{x}) + \text{im } S'(\bar{x}) - Q\}. \quad (19)$$

Robinson CQ ensures that

$$\mathcal{T}_D(\bar{x}) = \{d \in \mathbf{R}^n \mid S'(\bar{x})d \in \mathcal{T}_Q(S(\bar{x}))\}. \quad (20)$$

Furthermore, if Q is a closed convex cone and $\bar{x}$ is a local solution of the optimization problem (2) then there exists $v \in \mathbf{R}^s$ such that

$$\begin{aligned} f'(\bar{x}) + (S'(\bar{x}))^\top v &= 0, \quad S(\bar{x}) \in Q, \quad v \in Q^\circ, \\ \langle v, S(\bar{x}) \rangle &= 0. \end{aligned} \quad (21)$$

In the case of equality and inequality constraints (1), Robinson CQ (19) reduces to MFCQ (12), characterization of the tangent cone (20) reduces to equality (7), and optimality conditions (21) reduce to the KKT relations (10).

SECOND-ORDER NECESSARY OPTIMALITY CONDITIONS

CQs are also important for deriving second-order necessary optimality conditions. But not all CQs discussed in the section titled “Tangent Cone and First-Order Primal-Dual Optimality Conditions” are suitable for this purpose.

In this section the problem data is assumed to be twice continuously differentiable. Let $\bar{x} \in D$ be a local minimizer of f in D . We shall denote by $\mathcal{M}(\bar{x})$ the set of Lagrange multipliers at $\bar{x}$, that is, all $(\lambda, \mu) \in \mathbf{R}^l \times \mathbf{R}^m$ satisfying the KKT relations (10). Denote by

$$\begin{aligned} \mathcal{C}(\bar{x}) = \{d \in \mathbf{R}^n \mid & \langle f'(\bar{x}), d \rangle \leq 0, \quad h'(\bar{x})d = 0, \\ & \langle g'_i(\bar{x}), d \rangle \leq 0 \quad \forall i \in A(\bar{x})\}, \end{aligned}$$

the *critical cone* of the optimization problem at $\bar{x} \in D$. Then under MFCQ (12) it holds that

$$\begin{aligned} \forall d \in \mathcal{C}(\bar{x}) \quad \exists (\lambda, \mu) \in \mathcal{M}(\bar{x}) \\ \text{such that} \quad \left\langle \frac{\partial^2 L}{\partial x^2}(\bar{x}, \lambda, \mu)d, d \right\rangle \geq 0. \end{aligned} \quad (22)$$

It is known [23] that when SMFCQ does not hold (i.e., $\mathcal{M}(\bar{x})$ is not a singleton) the stronger version

$$\begin{aligned} \exists (\bar{\lambda}, \bar{\mu}) \in \mathcal{M}(\bar{x}) \quad \text{such that} \\ \left\langle \frac{\partial^2 L}{\partial x^2}(\bar{x}, \bar{\lambda}, \bar{\mu})d, d \right\rangle \geq 0 \quad \forall d \in \mathcal{C}(\bar{x}) \end{aligned} \quad (23)$$

is not a necessary optimality condition in general. At the same time, under CRCQ (14) even a stronger property than Relation (23) is valid [24]:

$$\begin{aligned} \forall (\lambda, \mu) \in \mathcal{M}(\bar{x}) \quad \left\langle \frac{\partial^2 L}{\partial x^2}(\bar{x}, \lambda, \mu)d, d \right\rangle \geq 0 \\ \forall d \in \mathcal{C}(\bar{x}). \end{aligned}$$

Weaker forms of second-order conditions make use of the subspace

$$\begin{aligned} \mathcal{C}^+(\bar{x}) = \{ & d \in \mathbf{R}^n \mid h'(\bar{x})d = 0, \\ & \langle g'_i(\bar{x}), d \rangle = 0 \forall i \in A(\bar{x}) \}, \end{aligned}$$

which is in general smaller than the critical cone $\mathcal{C}(\bar{x})$. The two cones coincide when the *strict complementarity* condition $\bar{\mu}_i > 0 \forall i \in A(\bar{x})$ holds. The following result had been established in Ref. 24. If $\bar{x}$ is a local minimizer satisfying KKT conditions (i.e., $\mathcal{M}(\bar{x}) \neq \emptyset$) and the weak constant rank condition holds, that is, there is a neighborhood U of $\bar{x}$ such that

the set $\{h'_i(x), i = 1, \dots, l\} \cup \{g'_i(x), i \in A(\bar{x})\}$
has the same rank for all $x \in U$,

then

$$\begin{aligned} \forall (\lambda, \mu) \in \mathcal{M}(\bar{x}) \quad & \left\langle \frac{\partial^2 L}{\partial x^2}(\bar{x}, \lambda, \mu) d, d \right\rangle \geq 0 \\ \forall d \in \mathcal{C}^+(\bar{x}). \end{aligned} \quad (24)$$

In particular, any CQ that ensures that $\mathcal{M}(\bar{x}) \neq \emptyset$ (see the section titled “Tangent Cone and First-Order Primal-Dual Optimality Conditions”) in combination with the weak constant rank condition, guarantees that condition (24) holds at a local minimizer $\bar{x}$. For example, condition (24) holds under rCRCQ (15), as the latter implies both $\mathcal{M}(\bar{x}) \neq \emptyset$ and the weak constant rank condition.

ERROR BOUNDS AND METRIC REGULARITY

Describing the local structure of a set D defined by a finite number of equality and inequality constraints (1) is also closely related to the so-called *error bounds*, which are estimates of the distance from a given point to the set D in terms of computable quantities measuring violation of its constraints. Specifically, one would like to know when there exist a neighborhood U of $\bar{x} \in D$ and a constant $c > 0$ such that

$$\text{dist}(x, D) \leq c(\|h(x)\| + \|\max\{0, g(x)\}\|) \quad \forall x \in U. \quad (25)$$

Indeed, if the condition (25) is valid then the consequences for the characterization of the tangent cone as in equality (7) are immediate. It is enough to observe that for $d \in \mathcal{L}_D(\bar{x})$ and $t > 0$ small enough it holds that $h(\bar{x} + td) = h(\bar{x}) + th'(\bar{x})d + o(t) = o(t)$, $g_i(\bar{x} + td) < 0$ for all $i \notin A(\bar{x})$ and $g_i(\bar{x} + td) = g_i(\bar{x}) + t\langle g'_i(\bar{x}), d \rangle + o(t) \leq o(t)$ for all $i \in A(\bar{x})$. Then condition (25) immediately implies that $\text{dist}(x + td, D) = o(t)$ so that $d \in \mathcal{T}_D(\bar{x})$.

In the case of linear constraints the error bound (25) (with $U = \mathbf{R}^n$) is the classical Hoffman’s Lemma [25]. More generally, condition (25) is valid under rCRCQ (15) [16,26]. The error bound is also valid assuming MFCQ (12) [10] or, more generally, CPLD (16) [16].

A stronger property than the error bound (25) is that of *metric regularity* [9,27]. Consider the right-hand side perturbation of the set D , that is,

$$\begin{aligned} D(p, q) = \{x \in \mathbf{R}^n \mid & h(x) = p, g(x) \leq q\}, \\ p \in \mathbf{R}^l, q \in \mathbf{R}^m. \end{aligned} \quad (26)$$

Let $\bar{x} \in D(0, 0)$. Then the system in Equation (26) is metrically regular at $(\bar{x}, 0, 0)$ if there exist a neighborhood V of $(\bar{x}, 0, 0)$ and a constant $C > 0$ such that

$$\begin{aligned} \text{dist}(x, D(p, q)) & \leq C(\|h(x) - p\| \\ & + \|\max\{0, g(x) - q\}\|) \quad \forall (x, p, q) \in V. \end{aligned}$$

For smooth constraint systems, metric regularity holds if, and only if, MFCQ (12) holds for the unperturbed set D defined in Equation (1) [10,28]. This is an important stability property that highlights the special role of MFCQ among all the other CQs.

Robinson CQ (19) for the more general smooth constraints (18) is also equivalent to metric regularity in the following sense. Defining the perturbed set

$$D(p) = \{x \in \mathbf{R}^n \mid S(x) + p \in Q\}, \quad p \in \mathbf{R}^s,$$

with $\bar{x} \in D(0)$, metric regularity holds at $(\bar{x}, 0)$ if there exist a neighborhood V of $(\bar{x}, 0)$ and a constant $C > 0$ such that

$$\text{dist}(x, D(p)) \leq C \text{dist}(S(x) + p, Q) \quad \forall (x, p) \in V.$$

SECOND-ORDER REGULARITY

CQs discussed until now were based on at most first-order information about the constraint functions. Sometimes, in particular when classical CQs are violated, second derivatives need to be employed.

One line of analysis is concerned with deriving second-order necessary optimality conditions of the type (22) under assumptions weaker than MFCQ (12). For a feasible set defined by Equation (1), the *second-order regularity condition* holds at $\bar{x} \in D$ in a direction $d \in \mathbf{R}^n$ if

$$\begin{aligned} & \text{the set } \{h'_i(\bar{x}), i = 1, \dots, l\} \text{ is linearly} \\ & \text{independent and } \exists \xi \in \mathbf{R}^n \text{ such that} \\ & h'(\bar{x})\xi + h''(\bar{x})[d, d] = 0, \\ & \langle g'_i(\bar{x}), \xi \rangle + \langle g''_i(\bar{x})d, d \rangle < 0 \quad \forall i \in A(\bar{x}). \end{aligned} \quad (27)$$

(see Ref. 29 for a different but equivalent statement of this property). It can be easily seen that condition (27) holds automatically in any direction $d \in \mathbf{R}^n$ provided MFCQ (12) holds at $\bar{x}$. But condition (27) may hold for a given $d \in \mathbf{R}^n$ when MFCQ is violated. When second-order regularity condition holds at $\bar{x}$ in a direction $d \in \mathcal{L}_D(\bar{x})$, one can constructively characterize the so-called *second-order tangent set in a direction d*, defined by

$$\mathcal{T}_2(\bar{x}, d) = \left\{ \xi \in \mathbf{R}^n \left| \begin{array}{l} \exists \{t_k\} \subset \mathbf{R}_+ \setminus \{0\}, \{t_k\} \rightarrow 0, \\ \exists \{\xi^k\} \subset \mathbf{R}^n, \{\xi^k\} \rightarrow \xi, \\ \text{such that } \bar{x} + t_k d + \frac{1}{2} t_k^2 \xi^k \in D \\ \text{for all } k \end{array} \right. \right\}.$$

Furthermore, for $d \in \mathcal{C}(\bar{x})$, this characterization allows to establish the second-order necessary optimality condition of the form

$$\begin{aligned} & \exists (\lambda, \mu) \in \mathcal{M}(\bar{x}) \quad \text{such that} \\ & \left\langle \frac{\partial^2 L}{\partial x^2}(\bar{x}, \lambda, \mu)d, d \right\rangle \geq 0. \end{aligned} \quad (28)$$

Note that the latter subsumes that $\mathcal{M}(\bar{x})$ is nonempty, which means that the KKT relations (10) hold as well.

Another important concept of second-order regularity was developed in Ref. 30,31 for the case when there are no inequality constraints, under the name of *2-regularity*.

In somewhat different terms, we say that this condition holds at $\bar{x} \in D$ in a direction $d \in \mathbf{R}^n$ if

$$\text{im } h'(\bar{x}) + h''(\bar{x})[d, \ker h'(\bar{x})] = \mathbf{R}^l.$$

The counterpart of this concept for problems with no equality constraints and the related theory were developed in Ref. 32. An extension of these works to the case of equality and inequality constraints, as in Equation (1), was derived in Ref. 33. Specifically, according to Arutyunov *et al.* [33], 2-regularity holds at $\bar{x} \in D$ in a direction $d \in \mathbf{R}^n$ if

$$\begin{aligned} & \text{im } h'(\bar{x}) + h''(\bar{x})[d, \mathcal{L}_D(\bar{x})] = \mathbf{R}^l \text{ and} \\ & \exists \xi^1 \in \mathbf{R}^n, \exists \xi^2 \in \mathcal{L}_D(\bar{x}) \text{ such that} \\ & h'(\bar{x})\xi^1 + h''(\bar{x})[d, \xi^2] = 0, \\ & \langle g'_i(\bar{x}), \xi^1 \rangle + \langle g''_i(\bar{x})d, \xi^2 \rangle < 0 \quad \forall i \in A(\bar{x}). \end{aligned} \quad (29)$$

As in the case of second-order regularity (27), 2-regularity (29) holds automatically in any direction $d \in \mathbf{R}^n$ provided MFCQ (12) holds at $\bar{x}$. But condition (29) may hold for a given $d \in \mathbf{R}^n$ when MFCQ is violated. The role of 2-regularity is to characterize those directions $d \in \mathcal{L}_D(\bar{x})$ that actually belong to $\mathcal{T}_D(\bar{x})$ in the cases when equality (7) does not hold. See Ref. 33 for the detailed exposition of the related theory of first- and second-order necessary optimality conditions, and in particular, for combinations of 2-regularity with second-order regularity and its relevant extensions. It is important to emphasize that, unlike second-order regularity, 2-regularity does not imply that relations (10) are necessary for optimality: $\mathcal{M}(\bar{x})$ can be empty, and the first- and second-order necessary optimality conditions that can be established under 2-regularity are generally weaker than relations (10) and (28), respectively.

Finally, in Ref. 34 the 2-regularity theory was extended to the general constraints, as in Equation (18). The corresponding condition of 2-regularity at $\bar{x} \in D$ in a direction $d \in \mathbf{R}^n$ has the form

$$\begin{aligned} & 0 \in \text{int } \{S(\bar{x}) + \text{im } S'(\bar{x}) \\ & \quad + S''(\bar{x})[d, (S'(\bar{x}))^{-1}(Q - S(\bar{x}))] - Q\}. \end{aligned}$$

It is clear that this condition is implied by Robinson CQ (19).

INTRODUCTION

A deterministic optimization problem may be formulated as

$$\min\{f(x)|x \in X, X \subseteq S\}, \quad (1)$$

where S, X, x , and f , respectively, denote the solution space, *feasible set*, a *feasible solution*, and a real-valued *objective function*. If S is a finite but large set, a *combinatorial optimization* problem is defined. If $S = \mathbb{R}^n$, we refer to continuous optimization. A solution $x^* \in X$ is *optimal* if $f(x^*) \leq f(x), \forall x \in X$. An *exact algorithm* for problem (1), if one exists, finds an optimal solution x^* , together with the proof of its optimality, or shows that there is no feasible solution, that is, $X = \emptyset$. Moreover, in practice, the time needed to do so should be finite (and not too long).

Metaheuristics are general frameworks to build heuristics for combinatorial and global optimization problems. Variable neighborhood search (VNS) [1–3] is a metaheuristic that systematically exploits the idea of neighborhood change, both in descent to local minima and in escape from the valleys that contain them.

The basic schemes of VNS and its extensions are simple and require few parameters. Therefore, in addition to providing very good solutions, often in simpler ways than other methods, VNS gives insight into the reasons for such a performance, which, in turn, can lead to more efficient and sophisticated implementations.

We first give preliminary results that are needed as a background to the article. Next, we review the basic rules of VNS (in the section titled “VNS–Basic Schemes”) and some of its recent extensions. In the section titled “Continuous VNS,” a description of VNS-based heuristics for continuous global optimization is given, as well as some computational results.

PRELIMINARIES

VNS is local search type metaheuristic. In this section, we will first give rules of classical local search, or steepest descent. A motivation for developing the global optimization technique VNS comes from the Variable metric method. This is an extension of steepest descent, developed for solving convex (local) optimization problems. Its rules are explained in the section titled “Variable Metric Method.” The section titled “Fixed Neighborhood Search” then gives rules of the simple local search type metaheuristic, known as *iterated local search* (ILS) or fixed neighborhood search (FNS).

Local Search

A *local search* heuristic consists in choosing an initial solution x , finding a direction of descent from x , within a neighborhood $N(x)$, and moving to the minimum of $f(x)$ within $N(x)$ in the same direction. If there is no direction of descent, the heuristic stops; otherwise, it is iterated. Usually, the steepest direction of descent, also referred to as *best improvement*, is used. This set of rules is summarized in Algorithm 1, where

```

Function LocalSearch( $x$ )
1 repeat
2    $x' \leftarrow x$ 
3    $x \leftarrow \arg \min_{y \in N(x')} f(y)$ 
   until ( $f(x) \geq f(x')$ )
4  $x \leftarrow x'$ 

```

Algorithm 1. Local search (steepest descent) heuristic.

we assume that an initial solution x is given. The output consists of a local minimum, also denoted by x , and its value.

Observe that a neighborhood structure $N(x)$ is defined for all $x \in X$. In discrete optimization problems, it usually consists of all vectors obtained from x by some simple modification, for example, in the case of 0–1 optimization, complementing one or two components of a 0–1 vector. Then, at each step, the neighborhood $N(x)$ of x is explored completely. As this may be time-consuming, an alternative is to use the *first descent* heuristic. Vectors $x_i \in N(x)$ are then enumerated systematically and a move is made as soon as a first direction of descent is found.

Variable Metric Method

The variable metric method for solving unconstrained continuous optimization problems has been suggested in Ref. 4 and independently in Ref. 5. The idea is to change the metric (and thus the neighborhood) at each iteration such that the search direction (steepest descent with respect to the current metric) adapts better to the local shape of the function. In the first iteration, a Euclidean unit ball in the n -dimensional solution space is used and the steepest descent (antigradient) direction found. At subsequent iterations, ellipsoidal balls are used and the steepest direction of descent is obtained with respect to a new metric resulting from a linear transformation. The purpose of such changes is to build up, iteratively, a good approximation to the inverse of the Hessian matrix A^{-1} of f , that is, to construct a sequence of matrices H_i with the property,

$$\lim_{i \rightarrow \infty} H_i = A^{-1}.$$

In the convex quadratic programming case, the limit is achieved after n iterations instead of an infinity of them. In this way, the so-called Newton search direction is obtained. The advantages are that (i) it is not necessary to find the inverse of the Hessian (which requires $O(n^3)$ operations) at each iteration and (ii) the second-order information is not needed.

Therefore, even in solving convex programs, a change of metric (and change of the neighborhoods induced by the metric) may produce efficient algorithms. The idea of neighborhood change for solving NP-hard problems may lead to even greater benefits.

Iterated Local Search

ILS [6], also known as *FNS* [7], is a step in between classical local search and variable metric on one side and VNS on the another. Instead of generating initial solutions completely at random, the next starting point for local search in ILS is a randomly generated solution taken from the vicinity of the best one found so far (incumbent solution). With this simple modification of the MLS, two advantages are obtained: (i) improved effectiveness: some of the solution attributes with good values in the incumbent are kept; (ii) improved efficiency: the next local search will have fewer iterations, as the incumbent will be in a deeper valley of the solution space. In order to find a perturbed solution, one needs to define a neighborhood structure $\mathcal{N}(x)$ differently than $N(x)$, the one used in the local search. The perturbed solution x' will belong to $\mathcal{N}(x)$. The ILS procedure is given in Algorithm 2.

Some extensions of the ILS Algorithm 2 are given in Ref. 8. Here the sharp acceptance criterion $f(x') \ll f_{\text{best}}$ is replaced with a more general one, allowing moves to solutions of worse quality than the incumbent x . Such deteriorating moves are also typical in the Tabu search method [9].

VNS–BASIC SCHEMES

VNS uses several neighborhoods in the search. Let us denote with $\mathcal{N}_k$, ($k = 1, \dots, k_{\text{max}}$), a finite set of preselected neighborhood structures, and with

```

Function ILS ( $x, t_{max}$ )
1  $f_{best} \leftarrow 10^{20}$ 
2 repeat
3   Generate perturb point  $x' \in \mathcal{N}(x)$  at random
4    $x' \leftarrow \text{LocalSearch}(x')$  /* Local search */
5   if  $f(x') < f_{best}$  then
6      $x \leftarrow x'; f_{best} = f(x)$ 
7    $t \leftarrow \text{CpuTime}()$ 
until  $t > t_{max}$ 

```

Algorithm 2. Steps of iterated local search.

$\mathcal{N}_k(x)$ the set of solutions in the k th neighborhood of x . We will also use the notation $N_\ell, \ell = 1, \dots, \ell_{\max}$, when describing local descent. Neighborhoods $\mathcal{N}_k$ or N_ℓ may be induced from one or more metric (or quasi-metric) functions introduced into the solution space S . An *optimal solution* x_{opt} (or global minimum) is a feasible solution where a minimum of problem (1) is reached. We call $x' \in X$ a *local minimum* of problem (1) with respect to $\mathcal{N}_k$, if there is no solution $x \in \mathcal{N}_k(x') \subseteq X$ such that $f(x) < f(x')$.

In order to solve problem (1) using several neighborhoods, the three observations listed below may be applied in a deterministic manner, a stochastic manner, or a combination of both. Indeed, VNS heavily relies upon these three observations:

- A local minimum with respect to one neighborhood structure is not necessarily a local minimum for another neighborhood structure.
- A global minimum is a local minimum with respect to all possible neighborhood structures.
- For many problems, local minima with respect to one or several neighborhoods are relatively close to each other.

We first give in Algorithm 3 the steps of the neighborhood change function that will be used later, and that is common to many VNS variants.

Function `NeighborhoodChange` (x, x', k) compares the new value $f(x')$ obtained from neighborhood $\mathcal{N}_k$ or N_l with the incumbent value $f(x)$ (line 1). If an improvement is

```

Function NeighborhoodChange ( $x, x', k$ )
1 if  $f(x') < f(x)$  then
2    $x \leftarrow x'; k \leftarrow 1$  /* Make a move */
  else
3    $k \leftarrow k + 1$  /* Next neighborhood */

```

Algorithm 3. Neighborhood change (or “Move or not”) function.

obtained, neighborhood counter k is returned to its initial value and the new incumbent updated (line 2). Otherwise, the next neighborhood is considered (line 3).

Variable Neighborhood Descent (VND)

The *variable neighborhood descent* (VND) method is obtained when the different specified neighborhoods are all examined in a deterministic way with a given order. Its steps are presented in Algorithm 4. In the descriptions of all algorithms that follow, we assume that an initial solution x is given. Note that the final solution should be a local minimum with respect to all $\ell_{\max}$ neighborhoods; hence, the chances to reach a global optimum are larger when using VND as compared with other heuristics that typically apply a single neighborhood structure. Note also that the order of neighborhoods that are used in a descent could be important, that is, a different order of the same set of neighborhoods may lead to different final results. Beside this *sequential* order of neighborhood structures in VND, one can develop a *nested* strategy. Assume, for example, that $\ell_{\max} = 3$. Then a possible nested strategy is to perform

```

Function VND ( $x, \ell_{max}$ )
1  $\ell \leftarrow 1$ 
2 repeat
3    $x' \leftarrow \arg \min_{y \in N_\ell(x)} f(y)$  /* Find the best solution in  $N_\ell(x)$  */
4   NeighborChange ( $x, x', \ell$ ) /* Change neighborhood */
until  $\ell = \ell_{max}$ 

```

Algorithm 4. Steps of the basic VND.

VND for the first two neighborhoods, in each point x' that belongs to the third ($x' \in N_3(x)$). Such an approach is successfully applied, for example, in Refs 10 and 11.

Reduced VNS

The *Reduced* VNS (RVNS) method is implemented when random points are selected from $\mathcal{N}_k(x)$ and no descent is made. Rather, the values of these new points are compared with that of the incumbent and updating takes place in case of improvement. We assume that a stopping condition has been chosen among various possibilities, for example, the maximum cpu time allowed t_{max} , or the maximum number of iterations between two improvements. To simplify the description of the algorithms, we always use t_{max} . Therefore, RVNS requires two parameters: t_{max} and k_{max} . Its steps are presented in Algorithm 5. With the function *Shake* represented in line 4, we generate a point x' at random from the k th neighborhood of x , that is, $x' \in \mathcal{N}_k(x)$.

RVNS is a useful method for very large instances where local search may be costly. It has been observed that the best value for

the parameter k_{max} is often 2. In addition, the maximum number of iterations between two improvements is usually used as a stopping condition. RVNS is akin to a Monte-Carlo method, but is more systematic. See, for example, [12] where the results for a continuous min–max problem obtained by RVNS are 30% better than those of a Monte-Carlo method. When applied to the p -median problem, RVNS gives solutions comparable to the *fast interchange* heuristic of [13] while being 20–40 times faster [14].

Basic VNS

The BVNS method [1] combines deterministic and stochastic changes of neighborhood. Its steps are given in Algorithm 6 (also see Figure 1).

Often successive neighborhoods $\mathcal{N}_k$ will be nested. Observe that point x' is generated at random in step 4 in order to avoid cycling, as might occur if a deterministic rule were applied. In step 5, a first improvement local search is usually adopted. However, it can be replaced with best improvement (Algorithm 1).

General VNS

Note that the Local search step 5 may also be replaced by VND (Algorithm 4). Using this general VNS (VNS/VND) approach has led to the most successful applications reported (see, recent surveys [3, 15]). The steps of GVNS are given in Algorithm 7.

CONTINUOUS VNS

We assume that $f : R^n \rightarrow R$ is a continuous function in Equation (1). No further assumptions are made on f . In particular, f does not need to be convex or smooth.

```

Function RVNS ( $x, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5     NeighborChange ( $x, x', k$ )
   until  $k = k_{max}$ 
6    $t \leftarrow \text{CpuTime}()$ 
until  $t > t_{max}$ 

```

Algorithm 5. Steps of the reduced VNS.

```

Function VNS ( $x, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$            /* Shaking */
5      $x'' \leftarrow \text{LocalSearch}(x')$     /* Local search */
6      $\text{NeighborhoodChange}(x, x'', k)$  /* Change neighborhood */
7   until  $k = k_{max}$ 
8    $t \leftarrow \text{CpuTime}()$ 
9 until  $t > t_{max}$ 

```

Algorithm 6. Steps of the basic VNS.

Figure 1. Basic VNS.

```

Function GVNS ( $x, \ell_{max}, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5      $x'' \leftarrow \text{VND}(x', \ell_{max})$ 
6      $\text{NeighborhoodChange}(x, x'', k)$ 
7   until  $k = k_{max}$ 
8    $t \leftarrow \text{CpuTime}()$ 
9 until  $t > t_{max}$ 

```

Algorithm 7. Steps of the general VNS.

Glob-VNS

Several VNS-based methods for solving continuous (un)constrained optimization problems have been proposed in the literature.

For example, radar polyphase code design is considered in Mladenović *et al.* [12], while Audet *et al.* [16] solve the bilinear (pooling) problem; Dražić *et al.* [17] suggest a VNS-based heuristic called **Glob-VNS** for solving general unconstrained optimization problems. Its pseudo-code is given in Algorithm 8.

Beside t_{max} and k_{max} , the choice of the local search solver may be seen as an additional parameter of **Glob-VNS**. The user can use one out of six well-known unconstrained methods offered in the software. Three of them are first-order methods (steepest descent, Fletcher–Reeves, variable metric) and three are direct search methods (Nelder–Mead, Hook–Jeves, Rosenbrock). In the Shaking step, there are two aspects that need to be considered. One is the set of

Figure 2. Ackley test function (AC2) over $[-2, 2] \times [-2, 2]$.

Figure 3. Rastrigin test function (RA2) over $[-1, 1] \times [-1, 1]$.

neighborhood structures $\mathcal{N}_k$ (induced from some metric such as the ℓ_p norm), while the other concerns how to take a random point from $\mathcal{N}_k(x)$. The second question relates

to the distribution $\mathcal{D}_j$ used. Neighborhood structures $\mathcal{N}_k$ are usually induced from the ℓ_∞ norm. Radii around the incumbent are found automatically, taking into account the

Function Glob-VNS (x, k_{max}, t_{max})

```

1 Select the set of neighborhood structures  $\mathcal{N}_k, k = 1, \dots, k_{max}$ 
2 Select the array of distribution types  $\mathcal{D}_j, j = 1, \dots, r$  and an initial point  $x \in X$ 
3  $f^* \leftarrow f(x), t \leftarrow 0$ 
4 while  $t < t_{max}$  do
5    $k \leftarrow 1$  // Initialize neighborhood counter  $k$ 
6   repeat
7     for all distribution types  $\mathcal{D}_j$  do
8        $x' \leftarrow \text{Shake}(x, k)$  // Get  $x' \in \mathcal{N}_k(x)$  at random with  $\mathcal{D}_j$  distribution
9        $x'' \leftarrow \text{LocalSearch}(x')$  // Apply Local Search to get a local minimum  $x''$ 
10      if  $f(x'') < f^*$  then
11         $x \leftarrow x'', f^* \leftarrow f(x''), \text{go to } 5$ 
12       $k \leftarrow k + 1$ 
13    until  $k = k_{max}$ 
14   $t \leftarrow \text{CpuTime}()$ 

```

Algorithm 8. Glob-VNS algorithm for unconstrained optimization.

box constraints: each coordinate is divided in k_{max} intervals from both sides of incumbent, forming k_{max} concentric hypercubes.

Gauss-VNS

Toskari and Guner [18] propose VNS variants that do not use metric distances to define neighborhoods; Mladenovic *et al.* [19] extend their unconstrained solver GLOB-VNS to the constrained case, using an exterior penalty function method; Audet *et al.* [16] and Bierlaire *et al.* [20] hybridize VNS with trust

region methods; Carrizosa *et al.* [21] modify GLOB-VNS by the so-called Gaussian VNS (Gauss-VNS), whose steps are given in Algorithm 9.

The paradigm of neighborhoods is generalized so that problems with unbounded domains can be addressed. The idea is to replace the class $\{\mathcal{N}_k(x)\}_{1 \leq k \leq k_{max}}$ of neighborhoods of point x by a class of *probability distributions* $\{\mathcal{P}_k(x)\}_{1 \leq k \leq k_{max}}$. The next random point in the shaking step is generated using the probability distribution $\mathcal{P}_k(x)$.

Function Gauss-VNS (x, k_{max}, t_{max})

```

1 Select the set of covariance matrices  $\Sigma_k, k = 1, \dots, k_{max}$ 
2 Select an initial point  $x \in X$ 
3  $f^* \leftarrow f(x), t \leftarrow 0$ 
4 while  $t < t_{max}$  do
5    $k \leftarrow 1$ 
6   repeat
7      $x' \leftarrow \text{Shake}(x, k)$  // Get  $x'$  from a Gaussian distribution with
8       // mean  $x$  and covariance matrix  $\Sigma_k$ 
9      $x'' \leftarrow \text{LocalSearch}(x')$  // Apply Local Search to get a local minimum  $x''$ 
10     $k \leftarrow k + 1$ 
11    if  $f(x'') < f^*$  then
12       $x \leftarrow x'', f^* \leftarrow f(x''), k \leftarrow 1$ 
13    until  $k = k_{max}$ 
14   $t \leftarrow \text{CpuTime}()$ 

```

Algorithm 9. Gauss-VNS algorithm for unconstrained optimization.

A comparison of two versions of VNS is conducted in Ref. 21 on the Ackley (ACn) function (see Figure 2 for $n = 2$):

$$\begin{aligned} f(x) &= 20 + e - 20 \exp \left(-0.2 \sqrt{\frac{1}{n} \sum_{i=1}^n x_i^2} \right) \\ &\quad - \exp \left(\frac{1}{n} \sum_{i=1}^n \cos(2\pi x_i) \right) \\ &- 15 \leq x_i \leq 30, i = 1, \dots, n, f_{\min} = 0, \end{aligned}$$

and Rastrigin function (RAn) (see Figure 3 for $n = 2$):

$$\begin{aligned} f(x) &= 10n + \sum_{i=1}^n (x_i^2 - 10 \cos(2\pi x_i)) \\ &- 5.12 \leq x_i \leq 5.12, i = 1, \dots, n, f_{\min} = 0. \end{aligned}$$

Results are reported in Table 1. Both methods used steepest descent local search (SD) and $k_{\max} = 10$ or 15. Global minima are found by both methods and for all test instances, but with a different number of function evaluations (or computer effort (ce)). The % deviation is calculated in the usual way: $(ce_{\text{glob}} - ce_{\text{gauss}})/ce_{\text{gauss}} \cdot 100\%$.

It appears that the Gauss-VNS method was able to find optimal solutions with much less effort than Glob-VNS, while the opposite is true for the Rastrigin function.

VNS with Modified Nelder–Mead as a Local Search

The weak point of both Glob-VNS and Gauss-VNS is the fact that the choice of a local search procedure is left to the user (steps 9 and 8 in Glob-VNS and Gauss-VNS, respectively). In order to make the VNS method more user friendly, a restarted modified Nelder–Mead (RMNM) method [22, 23] is suggested in Ref. 24 as the local search for any type of optimization problem. The basic ideas of RMNM are to (i) perform shrink move one vertex at a time, instead of moving all vertices in the direction of best; (ii) take parameter values $\alpha, \beta, \gamma, \delta$ at random from a given interval, that is, the next simplex vertex is obtained by

$$x_{\text{new}} = (1 + g) \cdot \bar{x} - g \cdot x_{n+1}, \quad (2)$$

where $\bar{x}$ is the centroid of the simplex $X = \{x_1, \dots, x_n, x_{n+1}\} \setminus \{x_{n+1}\}$, x_{n+1} a simplex vertex with the worst objective function value, and $g = \alpha, \alpha \cdot \beta, \alpha \cdot \gamma$ or $-\gamma$, expressing *reflection*, *expansion*, *inside contraction*, and *outside contraction*, respectively [23]; (iii) once the volume of the simplex is less than an arbitrarily small number ε , the procedure is restarted with the initial value of the simplex side length *size* unless no improvement has been reached from the previous big iteration. The steps of the RMNM used in the local search routine of Glob-VNS are given in Algorithm 10.

In step 2, the initial simplex $X = \{x_1, \dots, x_{n+1}\}$ is generated around a given point $x_1 \in R^n$, and then its vertices are ordered according to their quality ($f(x_1) \leq \dots \leq f(x_{n+1})$). If a Nelder–Mead iteration is unsuccessful, that is, if there is no point on the line that connects x_{n+1} and centroid $\bar{x}$ with better objective function value, we perform the shrink step only for one vertex x_j of the simplex X . Otherwise, the simplex is updated: the worst point is swapped with the new one, and all vertices of X are again ranked according to their objective function values. Once a local minimum is reached (a big iteration ends), the procedure is restarted with the same simplex size as the initial one, but now centered around the new local minimum. This restart procedure allows RMNM to attempt an escape from the current local minimum.

Nondifferentiable Test Instances

This user-friendly VNS-based method is compared in Ref. 24 with a Glob-VNS that uses standard NM as the local search. Ten nondifferentiable functions in high-dimensional space taken from Haarala [25] are examined as follows:

LND1. Generalization of MAXQ

$$f(x) = \max_{1 \leq i \leq n} x_i^2, f_{\text{opt}} = 0.$$

LND2. Generalization of MXHILB

$$f(x) = \max_{1 \leq i \leq n} \left| \sum_{j=1}^n \frac{x_j}{i+j-1} \right|, f_{\text{opt}} = 0.$$

Table 1. Comparison of Glob-VNS and Gauss-VNS on Ackley and Rastrigin Functions

Algorithm 10. Restarted Modified NM (RMNM).

LND3. Chained LQ

$$f(x) = \sum_{i=1}^{n-1} \max\{-x_i - x_{i+1}, -x_i - x_{i+1} + (x_i^2 + x_{i+1}^2 - 1)\}, f_{\text{opt}} = -(n-1)\sqrt{2}.$$

LND4. Chained CB3 I

$$f(x) = \sum_{i=1}^{n-1} \max\{x_i^4 + x_{i+1}^2, (2 - x_i)^2 + (2 - x_{i+1})^2, 2e^{-x_i + x_{i+1}}\}, f_{\text{opt}} = 2(n-1).$$

LND5. Chained CB3 II

$$f(x) = \max \left\{ \sum_{i=1}^{n-1} (x_i^4 + x_{i+1}^2), \sum_{i=1}^{n-1} ((2 - x_i)^2 + (2 - x_{i+1})^2), \sum_{i=1}^{n-1} (2e^{-x_i + x_{i+1}}) \right\}, f_{\text{opt}} = 2(n-1).$$

LND6. Number of active faces

$$f(x) = \max_{1 \leq i \leq n} \left\{ g \left(-\sum_{j=1}^n x_j \right), g(x_i) \right\}, g(y) = \ln(|y| + 1), f_{\text{opt}} = 0.$$

LND7. Nonsmooth generalization of Brown function 2

$$f(x) = \sum_{i=1}^{n-1} (|x_i|^{x_{i+1}^2+1} + |x_{i+1}|^{x_i^2+1}), f_{\text{opt}} = 0.$$

LND8. Chained Mifflin 2

$$f(x) = \sum_{i=1}^{n-1} (-x_i + 2(x_i^2 + x_{i+1}^2 - 1) + 1.75|x_i^2 + x_{i+1}^2 - 1|)$$

f_{opt} varies, $f_{\text{opt}} = -34.795$ for n
 $= 50$, $f_{\text{opt}} = -140.86$ for $n = 200$.

LND9. Chained crescent I

$$f(x) = \max \left\{ \sum_{i=1}^{n-1} (x_i^2 + (x_{i+1} - 1)^2 + x_{i+1} - 1), \right. \\ \left. \times \sum_{i=1}^{n-1} (-x_i^2 - (x_{i+1} - 1)^2 + x_{i+1} + 1) \right\}, f_{\text{opt}} = 0.$$

LND10. Chained crescent II

$$f(x) = \sum_{i=1}^{n-1} \max \{ x_i^2 + (x_{i+1} - 1)^2 + x_{i+1} - 1, \\ -x_i^2 - (x_{i+1} - 1)^2 + x_{i+1} + 1 \}, f_{\text{opt}} = 0.$$

These test functions are examined in different dimensional spaces with $n = 10, 20, 30, 40$, and 50 . The results are summarized in Table 2. The first two columns contain the dimension and the global optimum value of the test function. The results for each VNS variant are then presented in three successive columns. The first column (ce) contains the average number of overall function evaluations from 10 test runs. The second column (succ.) contains the number of runs where the global optimum is found with respect to desired precision

$$\frac{f_{\text{min}} - f_{\text{opt}}}{|f_{\text{min}}| + |f_{\text{opt}}| + 1} < \varepsilon_1, \quad \varepsilon_1 = 10^{-4}.$$

Local optima are detected if

$$\frac{f_{\max} - f_{\min}}{|f_{\max}| + |f_{\min}| + 1} < \varepsilon_2, \quad \varepsilon_2 = 10^{-5},$$

where $f_{\max}$ and $f_{\min}$ are the maximum and minimum function values, respectively, at the simplex vertices. If the optimal value is not found in all test runs, column ($f_{\min}$) contains the average solution value from 10 runs; otherwise this box is empty.

The results from Table 2 indicate that the more reliable method is VNS + RMNM. This method could not find an optimal solution within 10 restarts in only 2 out of 50 instances. For all 500 runs (50 instances $\times$ 10 restarts), it failed to reach optimality only 59 times. Even in these cases, the solutions found were very close to the global optima (within 10^{-3} precision).

CONCLUSIONS

Basic variants of the global optimization method, VNS, are first briefly discussed in this article. Then some recent VNS-based algorithms for solving continuous unconstrained optimization problems are given. They are computationally compared among themselves on standard differentiable and nondifferentiable test instances from the literature. The VNS procedures are found to be efficient and effective.

CONTINUOUS-TIME CONTROL UNDER STOCHASTIC UNCERTAINTY

STOCHASTIC CONTROL SYSTEMS

Optimal control and regulator problems arise in many concrete engineering applications (mechanical, electrical, thermodynamical, chemical, etc.) [1–5]. The basic control system (input–output system) is mathematically represented [5,6] by a system of first-order random differential equations:

$$\dot{z}(t) = g(t, \omega, z(t), u(t)), t_0 \leq t \leq t_f, \omega \in \Omega \quad (1a)$$

$$z(t_0) = z_0(\omega). \quad (1b)$$

Here, ω is the basic random element taking values in a probability space $(\Omega, \mathcal{A}, P)$, and describing the present random variations of model parameters and initial conditions, or the influence of noise terms. The probability space $(\Omega, \mathcal{A}, P)$ consists of the sample space or set of elementary events Ω , the σ -algebra $\mathcal{A}$ of events and the probability measure P . The plant state vector $z = z(t, \omega)$ is an m -vector involving measurable quantities like displacements, stresses, voltage, current, pressure, concentrations, and so on, $z_0(\omega)$ is the random initial state. The plant control $u(t)$ is a deterministic or stochastic n -vector denoting system inputs like external forces or moments, voltage, and so on. Furthermore, $\dot{z}$ denotes the derivative with respect to the time t . We assume that $u = u(t)$ is chosen such that $u(\cdot) \in U$, where U is a suitable linear subspace of the space $PC_0^n[t_0, t_f]$ of piecewise continuous functions $u(\cdot) : [t_0, t_f] \rightarrow \mathbb{R}^n$, normed by the maximum

norm. If $u = u(t, \omega), t_0 \leq t \leq t_f$, is a random input function, then correspondingly we suppose that $u(\cdot, \omega) \in U$ a.s. (almost sure) (with probability 1).

Let Z be a linear space of functions $z(\cdot) : [t_0, t_f] \rightarrow \mathbb{R}^m$ containing the set $PC_1^m[t_0, t_f]$ of possible trajectories of the plant; hence, the set of piecewise differentiable functions on the interval $[t_0, t_f]$, the space Z is also normed by the maximum norm. $D(\subset U)$ denotes the convex set of admissible controls $u(\cdot)$, defined for example, by some box constraints. Using the available information $\mathcal{A}_t$ up to a certain time t , the problem is then to find an optimal control $u^* = u^*(t)$ being most insensitive with respect to random parameter variations. This can be obtained by minimizing the (conditional) expected costs arising along the trajectory $z = z(t)$ and/or at the terminal state $z_f = z(t_f)$ subject to the plant differential equations (1a) and (1b) and the required control and state constraints. Optimal controls being most insensitive with respect to random parameter variations are also called *robust* optimal controls. Such controls can be obtained by stochastic optimization methods [7].

Since feedback control laws can be approximated very efficiently [3] by means of open-loop feedback (OLF) control laws, see the section titled “Control Laws”, for practical applications we may confine to the computation of deterministic stochastic optimal open-loop (OL) controls $u = u(t; t_b), t_b \leq t \leq t_f$, on arbitrary remaining time intervals $[t_b, t_f]$ of $[t_0, t_f]$. Here, $u(\cdot; t_b)$ is stochastic optimal with respect to the information $\mathcal{A}_{t_b}$ available at time t_b .

Random Differential Equations

Since in many technical applications the random input into the underlying dynamic equation, the control system, respectively, is not given via an additive white noise term, but by means of possibly time-dependent random parameters, in the following,

solutions of random differential equations, hence, solutions of *differential equations with random parameters*, are defined in the trajectory-wise sense [8].

In case of a *discrete* or *discretized* probability distribution of the random elements, model parameters, respectively, that is,

$$\begin{aligned}\Omega &= \{\omega_1, \omega_2, \dots, \omega_\varrho\}, P(\omega = \omega_j) = \alpha_j > 0, \\ j &= 1, \dots, \varrho, \sum_{j=1}^{\varrho} \alpha_j = 1,\end{aligned}$$

we can *redefine* Equations (1a) and (1b) by

$$\dot{z}(t) = g(t, z(t), u(t)), t_0 \leq t \leq t_f, \quad (1c')$$

$$z(0) = z_0 \quad (1d')$$

with the vectors and vector functions

$$\begin{aligned}z(t) &:= (z(t, \omega_j))_{j=1, \dots, \varrho}, \\ z_0 &:= (z_0(\omega_j))_{j=1, \dots, \varrho} \\ g(t, z, u) &:= (g(t, \omega_j, z(j), u))_{j=1, \dots, \varrho}, \\ z &:= (z(j))_{j=1, \dots, \varrho} \in \mathbb{R}^{q\varrho}.\end{aligned}$$

Hence, in this case, Equations (1c) and (1d) represent again an *ordinary* system of first order differential equations for the $q\varrho m$ unknown functions

$$z_{ij} = z_i(t, \omega_j), i = 1, \dots, m, j = 1, \dots, \varrho.$$

Results on the existence and uniqueness of solutions of the systems (1a), (1b) and (1c), (1d) and their dependence on inputs ξ can be found in Ref. 9.

Also in the general case we consider a *parametric approach* (solution in the point-wise sense). This means that for each random element $\omega \in \Omega$, Equations (1a) and (1b) is interpreted as a system of ordinary first-order differential equations with the initial values $z_0(\omega)$. Hence, we assume that to each deterministic control $u(\cdot) \in U$ and each random element $\omega \in \Omega$ there exists a unique measurable solution

$$z(t, \omega) = z^u(t, \omega) = z(t, \omega, u(\cdot)), t_0 \leq t \leq t_f, \quad (2a)$$

denoted, with the *solution or input-output operator* S , also by

$$z(\cdot, \omega) = S(\omega, u(\cdot))(\cdot), z(\cdot, \omega) \in PC_1^m[t_0, t_f], \quad (2b)$$

of the integral equation

$$\begin{aligned}z(t) &= z_0(\omega) + \int_{t_0}^t g(s, \omega, z(s), u(s)) ds, \\ t_0 &\leq t \leq t_f;\end{aligned} \quad (2c)$$

moreover, it is assumed that $(t, \omega) \rightarrow S(\omega, u(\cdot))(t)$ is measurable. Obviously, the integral Equation (2c) is the equivalent integral version of the initial value problems (1a) and (1b).

Parametric Representation of the Random Differential Equation. In order to justify the above assumptions, let the random input into the control system, as for example, a time-varying disturbance of the system, be described by an r -dimensional stochastic process $\theta = \theta(t, \omega)$, such that the sample functions $\theta(\cdot, \omega)$ are continuous with probability one. Furthermore, let

$$\tilde{g} : [t_0, t_f] \times \mathbb{R}^r \times \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R}^m$$

be a continuous m -vector function having continuous Jacobians $D_\theta \tilde{g}, D_z \tilde{g}, D_u \tilde{g}$ with respect to θ, z, u . Now consider the *parametric case* that the function g of the process differential equations (1a) and (1b) is given by

$$g(t, \omega, z, u) := \tilde{g}(t, \theta(t, \omega), z, u),$$

$(t, \omega, z, u) \in [t_0, t_f] \times \Omega \times \mathbb{R}^m \times \mathbb{R}^n$. Furthermore, put $U = C^m[t_0, t_f], Z = C_0^m[t_0, t_f]$, and $\Theta = C_0^r[t_0, t_f]$, where $C_0^v[t_0, t_f]$ denotes the space of all continuous functions of $[t_0, t_f]$ into $\mathbb{R}^v$ normed by the supremum norm $\|\cdot\|_\infty$. By our assumption we have $\theta(\cdot, \omega) \in \Theta$ a.s. Define

$$\Xi = \mathbb{R}^m \times \Theta \times U;$$

Ξ is the space of *model and environmental parameters* of the dynamic system. Hence, Ξ may also be interpreted as the *total space*

of inputs $\xi = (z_0, \theta(\cdot), u(\cdot))$ into the dynamic equation, consisting of the random initial state z_0 , the random input function $\theta = \theta(t, \omega)$ and the control input $u = u(t)$. Now, let the mapping $\tau : \Xi \times Z \rightarrow Z$ related to the plant equations (1a) and (1b) or (2c) be defined by

$$\begin{aligned} \tau(\xi, z(\cdot))(t) \\ = z(t) - \left(z_0 + \int_{t_0}^t \tilde{g}(s, \theta(s), z(s), u(s)) ds \right), \\ t_0 \leq t \leq t_f. \end{aligned} \quad (2d)$$

Obviously, the initial value problems (1a) and (1b) or its integral form (2c) can be represented by the operator equation

$$\tau(\xi, z(\cdot)) = 0. \quad (2e)$$

Operators of the type (2d) are well studied [10]. It is known that τ is *continuously Fréchet (F)-differentiable* [9,10]. Note that the F-differential is just a generalization of the derivatives (Jacobians) of mappings between finite-dimensional spaces to mappings between arbitrary-normed spaces. Thus, the F-derivative $D\tau$ of τ at a certain point $(\bar{\xi}, \bar{z}(\cdot))$ is given by

$$\begin{aligned} \left(D\tau(\bar{\xi}, \bar{z}(\cdot)) \cdot (\xi, z(\cdot)) \right)(t) = z(t) \\ - \left(z_0 + \int_{t_0}^t D_z \tilde{g}(s, \bar{\theta}(s), \bar{z}(s), \bar{u}(s)) z(s) ds \right. \\ + \int_{t_0}^t D_\theta \tilde{g}(s, \bar{\theta}(s), \bar{z}(s), \bar{u}(s)) \theta(s) ds \\ + \left. \int_{t_0}^t D_u \tilde{g}(s, \bar{\theta}(s), \bar{z}(s), \bar{u}(s)) u(s) ds \right), \\ t_0 \leq t \leq t_f, \end{aligned} \quad (2f)$$

where $\bar{\xi} = (\bar{z}_0, \bar{\theta}(\cdot), \bar{u}(\cdot))$ and $\xi = (z_0, \theta(\cdot), u(\cdot))$. Obviously, the F-derivative $D\tau$ of τ , here described in the form of a directional derivative of τ at $(\bar{\xi}, \bar{z}(\cdot))$ in the direction of $(\xi, z(\cdot))$, is represented by means of the Jacobians $D_z \tilde{g}$, $D_\theta \tilde{g}$, $D_u \tilde{g}$ of $\tilde{g}$. Especially, for the F-derivative of τ with respect to $z(\cdot)$ we

find

$$\begin{aligned} \left(D_z \tau(\bar{\xi}, \bar{z}(\cdot)) \cdot z(\cdot) \right)(t) \\ = z(t) - \int_{t_0}^t D_z \tilde{g}(s, \bar{\theta}(s), \bar{z}(s), \bar{u}(s)) z(s) ds, \\ t_0 \leq t \leq t_f. \end{aligned}$$

The related integral equation

$$D_z \tau(\bar{\xi}, \bar{z}(\cdot)) \cdot z(\cdot) = y(\cdot), y(\cdot) \in Z,$$

is a linear Volterra integral equation. By our assumptions this equation has a unique solution $z(\cdot) \in Z$ [11]. Therefore, $D_z \tau(\bar{\xi}, \bar{z}(\cdot))$ is a linear, continuous one-to-one map from Z onto Z . Hence, its inverse exists. This property enables then the application of the implicit function theorem [9,10] to the equation $\tau(\xi, S(\xi)) = 0$, where the following assumptions are still needed.

Assumption 1. Let $(\bar{\xi}, \bar{z}(\cdot)) \in \Xi \times Z$ be a pair of a reference parameter vector and a reference trajectory of Equations (1a) and (1b) such that $\tau(\bar{\xi}, \bar{z}(\cdot)) = 0$. Hence, $\bar{z}(\cdot)$ is the solution of

$$\dot{z}(t) = \tilde{g}(t, \bar{\theta}(t), z(t), \bar{u}(t)), t_0 \leq t \leq t_f, \quad (3a)$$

$$z(t_0) = \bar{z}_0, \quad (3b)$$

where $\bar{\xi} = (\bar{z}_0, \bar{\theta}(\cdot), \bar{u}(\cdot))$.

This assumption means that for the given reference or nominal system input $\bar{\xi}$, the basic system differential equations (1a) and (1b) has the solution $\bar{z} = \bar{z}(t)$. On the basis of this and the former assumptions on $\tilde{g}$, results on the existence and uniqueness of solutions of the system of differential equations for all inputs ξ in a certain neighborhood of $\bar{\xi}$ follow now from the fixed point theorem and the method of successive approximation (Picard–Lindelöf) [9]:

Lemma 1 [Existence and uniqueness of solutions of the system differential equation]. Under Assumption 1 there exists an open neighborhood $V(\bar{\xi})$ of $\bar{\xi}$, and a unique

continuous mapping $S : V(\bar{\xi}) \rightarrow Z$ such that (a) $S(\bar{\xi}) = \bar{z}(\cdot)$; (b) $\tau(\xi, S(\xi)) = 0$ for each $\xi \in V(\bar{\xi})$, that is, $z(t) := S(\xi)(t)$, $t_0 \leq t \leq t_f$, is the unique solution of

$$z(t) = z_0 + \int_{t_0}^t \tilde{g}(s, \theta(s), z(s), u(s)) ds, \quad t_0 \leq t \leq t_f, \quad (3c)$$

where $\xi = (z_0, \theta(\cdot), u(\cdot))$.

Application of the implicit function theorem [9] to the Equation (2e) yields then this result.

Lemma 2 [Differentiation of trajectories with respect to system inputs]. Under the assumptions mentioned in the above lemma, the solution $z(t) = S(\xi)(t)$ of the system differential equations (1a) and (1b) is continuously F -differentiable on $V(\bar{\xi})$, and the partial F -derivative $\zeta(\cdot) = \zeta_{u,h} = D_u S(\xi)h(\cdot)$ with respect to the control $u(\cdot)$ and in the direction of a function $h(\cdot) \in U$ satisfies the integral equation

$$\begin{aligned} \zeta(t) &= \int_{t_0}^t D_z \tilde{g}(s, \theta(s), S(\xi)(s), u(s)) \zeta(s) ds \\ &= \int_{t_0}^t D_u \tilde{g}(s, \theta(s), S(\xi)(s), u(s)) h(s) ds, \\ t_0 \leq t \leq t_f, \end{aligned} \quad (3d)$$

where $\xi = (z_0, \theta(\cdot), u(\cdot))$.

Remark 1. Taking the time derivative of Equation (3d) shows that this integral equation is equivalent to the so-called *perturbation equation* needed in the section titled “Computation of Directional Derivatives”.

Objective Function

In order to obtain optimal controls $u = u(t)$, $t_0 \leq t \leq t_f$, being *robust*, that is, most insensitive with respect to stochastic variations of the model and environmental parameters of the process, the cost criterion

$F = F(u(\cdot))$ related to the controlled process $z = z(t, \omega)$ is defined by the expectation

$$F(u(\cdot)) := Ef(\omega, S(\omega, u(\cdot)), u(\cdot)). \quad (4a)$$

Here, $E = E(\cdot | \mathcal{A}_{t_0})$, denotes the conditional expectation given the information $\mathcal{A}_{t_0}$ about the control process up to the considered starting time point t_0 . Moreover, $f = f(\omega, z(\cdot), u(\cdot))$ denotes the stochastic total costs arising along the trajectory $z = z(t, \omega)$ and at the terminal point $z_f = z(t_f, \omega)$ [1,5]. Hence,

$$\begin{aligned} f(\omega, z(\cdot), u(\cdot)) &:= \int_{t_0}^{t_f} L(t, \omega, z(t), u(t)) dt \\ &+ G(t_f, \omega, z(t_f)), \end{aligned} \quad (4b)$$

$z(\cdot) \in Z, u(\cdot) \in U$. Here,

$$\begin{aligned} L : [t_0, t_f] \times \Omega \times \mathbb{R}^m \times \mathbb{R}^n &\rightarrow \mathbb{R}, \\ G : [t_0, t_f] \times \Omega \times \mathbb{R}^m &\rightarrow \mathbb{R} \end{aligned}$$

are given measurable cost functions. We suppose that $L(t, \omega, \cdot, \cdot)$ and $G(t, \omega, \cdot)$ are convex functions for each $(t, \omega) \in [t_0, t_f] \times \Omega$, having continuous partial derivatives $\nabla_z L(\cdot, \omega, \cdot, \cdot)$, $\nabla_u L(\cdot, \omega, \cdot, \cdot)$, $\nabla_z G(\cdot, \omega, \cdot)$. Note that in this case

$$\begin{aligned} (z(\cdot), u(\cdot)) &\rightarrow \int_{t_0}^{t_f} L(t, \omega, z(t), u(t)) dt \\ &+ G(t_f, \omega, z(t_f)) \end{aligned} \quad (4c)$$

is a convex function on $Z \times U$ for each $\omega \in \Omega$. Moreover, assume that the expectation $F(u(\cdot))$ exists and is finite for each admissible control $u(\cdot) \in D$.

Example 1. In the case of active structural control or for optimal regulator design of robots, cf. Refs 2,4, and 12, the total cost function f is given by defining the individual cost functions L and G as follows:

$$L(t, \omega, z, u) := z^T Q(\omega)z + u^T R(\omega)u \quad (4d)$$

$$G(t_f, \omega, z) := G(z). \quad (4e)$$

Here, Q and R , respectively, are certain positive (semi)definite $m \times m, n \times n$ matrices which may depend also on (t, ω) . Moreover, the terminal cost function G depends then only on z . For example, in case of end point control, the cost function $G(z)$ is given by

$$G(z) = (z - z_f)^T G_f (z - z_f), \quad (4f)$$

with a certain desired, possibly random terminal point z_f and a positive (semi)definite weight matrix G_f .

In this article, we now present methods for the approximate solution for the following minimum expected cost problems: Find a control $u(\cdot)$ solving

$$\min F(u(\cdot)) \text{ s.t. } u(\cdot) \in D. \quad (5)$$

Problem (5) is equivalent to $(E = E(\cdot | \mathcal{A}_{t_0}))$ [13,14],

$$\begin{aligned} \min E \left(\int_{t_0}^{t_f} L(t, \omega, z(t), u(t)) dt \right. \\ \left. + G(t_f, \omega, z(t_f)) | \mathcal{A}_{t_0} \right) \end{aligned} \quad (6a)$$

s.t.

$$\dot{z}(t) = g(t, \omega, z(t), u(t)), t_0 \leq t \leq t_f, \text{ a.s.} \quad (6b)$$

$$z(t_0, \omega) = z_0(\omega), \text{ a.s.} \quad (6c)$$

$$u(\cdot) \in D. \quad (6d)$$

In order to get *robust* optimal controls/regulators, random variations of the model, environmental and applied load parameters, as well as random variations of initial values are incorporated into the optimal control design process by means of stochastic optimization methods. Hence, we use the following notion.

Definition 1. An optimal solution $u^*(\cdot)$ of the optimal control problem (5) or (6a)–(6d) is called a *stochastic optimal control*.

Control Laws

In optimal control of dynamic systems the following types of *control laws* are mostly considered:

1. *Open-Loop Control.* Here, the control function $u = u(t)$ is a *deterministic* function depending only on the given (*a priori*) information $\mathcal{A}_{t_0} \subset \mathcal{A}$ about the system, the model parameters, the initial values, respectively, available at the starting or reference time point t_0 . Hence, for the optimal selection of optimal (OL) controls

$$u(t) = u(t; (t_0, \mathcal{A}_{t_0})), t \geq t_0, \quad (7a)$$

we get optimal control problems of type (5).

2. *Closed-Loop Control.* In this case, the control function $u = u(t)$ is a **stochastic** function

$$u = u(t, \omega) = u(t, \mathcal{A}_t), t \geq t_0 \quad (7b)$$

depending on time t and the total information $\mathcal{A}_t$ on the system available up to time t . Especially $\mathcal{A}_t$ may contain information about the state $z(t) = z(t, \omega)$ up to time t .

3. *Open-Loop Feedback Control.* In this combination of OL and CL control, at each time point $t_b \geq t_0$, first the optimal OL control function for the remaining time interval $t_b \leq t \leq t_b$ is computed, hence,

$$u_{[t_b, t_f]}(t) = u(t; (t_b, \mathcal{A}_{t_b})), t \geq t_b. \quad (7c)$$

Evaluating then the obtained optimal OL control $u_{[t_b, t_f]}(\cdot)$ only at $t_b = t$, the OLF control is defined by

$$u(t, \omega) := u_{[t, t_f]}(t) = u(t; (t, \mathcal{A}_t)), t \geq t_0, \quad (7d)$$

that is, the OL control $u_{[t, t_f]}(s)$, $s \geq t$, for the remaining time interval $[t, t_f]$ is used only for $s = t$. Stochastic optimal (OLF) controls are therefore obtained

Figure 1. Remaining time interval.

by solving again control problems of the type (5). Note that OLF control is the basic tool in the so-called *model predictive control* [3], which is often applied in practice.

Remark 2. In case of OLF control, the initial time point t_0 in the expected total cost function is replaced by the intermediate starting time point t_b of the remaining time intervals $[t_b, t_f]$, see Fig. 1.

Discrete-Time Controllers. In practice, fast, light, accurate, versatile, and economical control laws are often implemented in digital form. Thus, the design of digital or discrete-time controllers is an important problem for practical applications. As discussed in Ref. 15, there are two important design approaches for digital control: direct discrete-time controller design, which is not considered in the present work, and controller redesign of continuous-time controllers as discussed in this article. This second method is very appealing since any technique for continuous-time control can be used to construct an appropriate continuous-time controller, which is then discretized and implemented on a corresponding control device.

CONVEX APPROXIMATION

First, we observe that problem (5) is in general a nonconvex optimization problem [10]. Since for convex (deterministic) optimization problems there is a well-established theory, we consider the approximation of the original problem (5) by suitable convex problems. Initially, we describe below the basic steps of this procedure [30]. Moreover, the construction of descent directions for F at a reference

control and the derivation of necessary optimality conditions for optimal solutions of the control problem (5) are considered.

Let $v(\cdot) \in D$ be an arbitrary, but fixed admissible initial or reference control and assume, see Lemma 1.

Assumption 2. $S(\omega, \cdot)$ is F -differentiable at $v(\cdot)$ for each $\omega \in \Omega$.

Denoting the F -derivative of $S(\omega, \cdot)$ at $v(\cdot)$ by $DS(\omega, v(\cdot))$, the expected total cost function $F = F(u(\cdot))$ is replaced now, see Fig. 2, by

$$F_{v(\cdot)}(u(\cdot)) := Ef(\omega, S(\omega, v(\cdot)) + DS(\omega, v(\cdot)) \times (u(\cdot) - v(\cdot)), u(\cdot)), \quad (8)$$

where $u(\cdot) \in U$, assuming that $F_{v(\cdot)}(u(\cdot)) \in \mathbb{R}$ for all pairs $(u(\cdot), v(\cdot)) \in D \times D$.

Then, problem (5) is approximated [13] by

$$\min F_{v(\cdot)}(u(\cdot)) \text{ s.t. } u(\cdot) \in D. \quad ((5)_{v(\cdot)})$$

Next, a decisive property of this problem is shown:

Lemma 3. *Problem $(5)_{v(\cdot)}$ is a convex optimization problem.*

Proof. According to the section titled “Objective Function”, function (4c) is convex. The assertion now follows from the linearity of the F -differential.

Remark 3. The approximate $F_{v(\cdot)}$ of F is obtained from Equations (4a) and (4b) by means of linearization of the input–output map $S = S(\omega, u(\cdot))$ with respect to the control $u(\cdot)$ at the nominal or reference control $v(\cdot)$. Hence, the convex approximation $F_{v(\cdot)}$ of F follows by *inner linearization* of the control problem with respect to the control $u(\cdot)$ at $v(\cdot)$.

Let $\phi'_+(x; y)$ denote the directional derivative at $x \in X$ and in direction $y \in X$ of a convex

Figure 2. Convex approximation.

function $\phi : X \rightarrow \mathbb{R}$, where X is a linear space [16]. With this definition, from Lemma 3 we may infer that for all $u(\cdot), v(\cdot) \in D$ and $h(\cdot) \in U$ the directional derivative of $F_{v(\cdot)}$ is given by

$$\begin{aligned} F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ = Ef'_+(\omega, S(\omega, v(\cdot)) + DS(\omega, v(\cdot))(u(\cdot) - v(\cdot)), \\ u(\cdot); DS(\omega, v(\cdot))h(\cdot), h(\cdot)). \end{aligned} \quad (9)$$

A solution $\bar{u}(\cdot) \in D$ of Equation (5)_{v(·)} is then characterized by

$$F'_{v(\cdot)+}(\bar{u}(\cdot); u(\cdot) - \bar{u}(\cdot)) \geq 0 \text{ for all } u(\cdot) \in D. \quad (10)$$

For each $v(\cdot) \in D$, let $M(v(\cdot))$ be the set of solutions of problem (5)_{v(·)}.

Assumption 3. $M(v(\cdot)) \neq \emptyset$ for each $v(\cdot) \in D$.

The relation between our original problem (5) and the family of its approximates (5)_{v(·)}, $v(\cdot) \in D$, is described by the following conditions.

Theorem 1. Optimality conditions. Suppose that

$$F'_+(\bar{u}(\cdot); h(\cdot)) = F'_{v(\cdot)+}(\bar{u}(\cdot); h(\cdot)) \quad (11)$$

for each $v(\cdot) \in D$ and $h(\cdot) \in U$. Then

- (a) If $\bar{u}(\cdot)$ is an optimal control, then $\bar{u}(\cdot) \in M(\bar{u}(\cdot))$, that is, $\bar{u}(\cdot)$ is a solution of (5) _{$\bar{u}(\cdot)$} .
- (b) If problem (5) is convex, then $\bar{u}(\cdot)$ is an optimal control if and only if $\bar{u}(\cdot) \in M(\bar{u}(\cdot))$.

Sufficient conditions for the important Condition (11) can be found [14] as follows. By Equations (4a) and (4b), and (9) we have

$$\begin{aligned} F'_{v(\cdot)+}(v(\cdot); h(\cdot)) \\ = Ef'_+(\omega, S(\omega, v(\cdot)), v(\cdot); DS(\omega, v(\cdot))h(\cdot), h(\cdot)) \\ = E \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left(f(\omega, S(\omega, v(\cdot) + \varepsilon h(\cdot)), v(\cdot) + \varepsilon h(\cdot)) \right. \\ \left. - f(\omega, S(\omega, v(\cdot)), v(\cdot)) \right). \end{aligned} \quad (12)$$

If the function $f = f(\omega, z(\cdot), u(\cdot))$ is (F-) differentiable with respect to $(z(\cdot), u(\cdot))$, the above Equation (12) can also be obtained by the chain rule [9,10]. On the basis of Equation (12), sufficient conditions for Equation (11) can then be derived as follows.

Lemma 4. Condition (11) in Theorem 1 holds if and only if the expectation operator “E” and the limit process “ $\lim_{\varepsilon \downarrow 0}$ ” in Equation (12) may be interchanged.

The interchangeability needed in Lemma 4 holds, for example, if $\sup \left\{ \|DS(\omega, v(\cdot) + \right.$

$\varepsilon h(\cdot) \| : 0 \leq \varepsilon \leq 1 \}$ is bounded with probability one, and the convex function $f(\omega, \cdot, \cdot)$ satisfies a Lipschitz condition

$$\begin{aligned} & \left| f(\omega, z(\cdot), u(\cdot)) - f(\omega, \bar{z}(\cdot), \bar{u}(\cdot)) \right| \\ & \leq \gamma(\omega) \left\| (z(\cdot), u(\cdot)) - (\bar{z}(\cdot), \bar{u}(\cdot)) \right\|_{\infty} \end{aligned}$$

on a set $Q \subset Z \times U$ containing all vectors $(S(\omega, v(\cdot) + \varepsilon h(\cdot)), v(\cdot) + \varepsilon h(\cdot))$, $0 \leq \varepsilon \leq 1$, where $E\gamma(\omega) < +\infty$. Further conditions were derived in Ref. 14.

Admissible descent directions can be constructed by applying this result.

Lemma 5.

(a) If $\bar{u}(\cdot) \notin M(\bar{u}(\cdot))$ for a control $\bar{u}(\cdot) \in D$, then

$$\begin{aligned} F_{\bar{u}(\cdot)}(u(\cdot)) & < F_{\bar{u}(\cdot)}(\bar{u}(\cdot)) \\ & = F(\bar{u}(\cdot)) \text{ for each } u(\cdot) \in M(\bar{u}(\cdot)) \end{aligned}$$

(b) Let the controls $u(\cdot), v(\cdot) \in D$ be related such that

$$F_{u(\cdot)}(v(\cdot)) < F_{u(\cdot)}(u(\cdot)).$$

Provided that Equation (11) holds for the pair $(u(\cdot), h(\cdot))$, $h(\cdot) = v(\cdot) - u(\cdot)$, then $h(\cdot)$ is an admissible direction of decrease for F at $u(\cdot)$, that is, we have $F(u(\cdot) + \varepsilon h(\cdot)) < F(u(\cdot))$ and $u(\cdot) + \varepsilon h(\cdot) \in D$ on a suitable interval $0 < \varepsilon < \bar{\varepsilon}$.

Proof. See Refs 13 and 14.

Points, controls, and so on, fulfilling at least the necessary optimality conditions of a certain optimization problem are candidates for optimal solutions. Hence, due to the relations shown in Theorem 1, the following notion is used [10,17]:

Definition 2. A control $u(\cdot) \in D$ fulfilling the necessary optimality condition $u(\cdot) \in M(u(\cdot))$ is called a stationary control.

Remark 4. Under the rather weak assumptions in Theorem 1, an optimal control is also stationary, and in the case of a convex problem (5) the two concepts coincide. Hence, *stationary controls are candidates for stochastic optimal controls*. As an appropriate approximate for a stochastic optimal control, we will determine therefore stationary controls [10,18]. Note that stationary admissible decisions may be constructed numerically by means of conditional gradient-type algorithms [17,19].

In order to apply now, the optimality conditions of Theorem 1, hence, to construct stationary controls, according to condition (10) we need the directional derivative $F'_{v(\cdot)+}$ of the convex approximate $F_{v(\cdot)}$ of the expected total cost function F of the control problem.

COMPUTATION OF DIRECTIONAL DERIVATIVES

According to Definition 2 of a stationary control and characterization (10) of an optimal solution of Equation (5)_{v(·)}, we first have to determine the directional derivative $F'_{v(\cdot)+}$. On the basis of the justification in the section titled “Stochastic Control Systems”, we assume again that the solution $z(t, \omega) = S(\omega, u(\cdot))(t)$ of Equation (2c) is measurable in (t, ω) for each $u(\cdot) \in D$, $u(\cdot) \rightarrow S(\omega, u(\cdot))$ is continuously differentiable on D for each $\omega \in \Omega$. Furthermore, we suppose that the F -differential $\zeta(t, \omega) = (D_u S(\omega, u(\cdot))h(\cdot))(t)$, $h(\cdot) \in U$, is measurable in (t, ω) , and is given according to Equations (3a)–(3d) by the *linear perturbation equation*

$$\begin{aligned} \dot{\zeta}(t) & = A(t, \omega, u(\cdot))\zeta(t) + B(t, \omega, u(\cdot))h(t), \\ t_0 & \leq t \leq t_f, \omega \in \Omega \end{aligned} \quad (13a)$$

$$\zeta(t_0) = 0 \quad (13b)$$

with the Jacobians

$$A(t, \omega, u(\cdot)) := D_z g(t, \omega, z^u(t, \omega), u(t)) \quad (13c)$$

$$B(t, \omega, u(\cdot)) := D_u g(t, \omega, z^u(t, \omega), u(t)) \quad (13d)$$

and $z^u(t, \omega)$ defined by

$$z^u(t, \omega) := S(\omega, u(\cdot))(t), \quad (13e)$$

$(t, \omega, u(\cdot)) \in [t_0, t_f] \times \Omega \times U$. The solution $\zeta = \zeta(t, \omega)$ of Equations (13a) and (13b) is also denoted by

$$\begin{aligned} \zeta(t, \omega) &= \zeta_{u,h}(t, \omega) \\ &:= \left(D_u S(\omega, u(\cdot)) h(\cdot) \right)(t), h(\cdot) \in U. \end{aligned} \quad (13f)$$

This means that the approximate $(5)_{v(\cdot)}$ of Equation (5) has the following explicit form:

$$\begin{aligned} \min E \Big(& \int_{t_0}^{t_f} L(t, \omega, z^v(t, \omega) + \zeta(t, \omega), u(t)) dt + \\ & + G(t_f, \omega, z^v(t_f, \omega) + \zeta(t_f, \omega)) \Big) \end{aligned} \quad (14a)$$

s.t.

$$\begin{aligned} \dot{\zeta}(t, \omega) &= A(t, \omega, v(\cdot)) \zeta(t, \omega) \\ &+ B(t, \omega, v(\cdot)) (u(t) - v(t)) \text{ a.s.} \end{aligned} \quad (14b)$$

$$\zeta(t_0, \omega) = 0 \text{ a.s.} \quad (14c)$$

$$u(\cdot) \in D. \quad (14d)$$

With the convexity assumptions in the section titled “Objective Function”, Lemma 3 yields that problem (14a)–(14d) is a convex stochastic control problem, with a *linear* dynamic equation. For the subsequent analysis of the stochastic control problem, we need a representation of the directional derivative $F'_{v(\cdot)+}(u(\cdot); h(\cdot))$ by a scalar product of the increment function $h(\cdot)$ with a certain deterministic vector function $q = q(t)$.

From representation (9) of the directional derivative $F'_{v(\cdot)+}$ of the convex approximate $F_{v(\cdot)}$ of F and definition (4b) of $f = f(\omega, z(\cdot), u(\cdot))$, with Equation (13f) we

obtain

$$\begin{aligned} & F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ &= E \left(\int_{t_0}^{t_f} \left(\nabla_z L(t, \omega, z^v(t, \omega) + \zeta_{v,u-v}(t, \omega), u(t)) \right)^T \right. \\ &\quad \times \zeta_{v,h}(t, \omega) \\ &\quad + \nabla_u L(t, \omega, z^v(t, \omega) + \zeta_{v,u-v}(t, \omega), u(t))^T h(t) dt \\ &\quad + \nabla_z G(t_f, \omega, z^v(t_f, \omega) + \zeta_{v,u-v}(t_f, \omega))^T \\ &\quad \left. \times \zeta_{v,h}(t_f, \omega) \right). \end{aligned} \quad (15)$$

Defining the gradients

$$\begin{aligned} a(t, \omega, v(\cdot), u(\cdot)) &:= \nabla_z L(t, \omega, z^v(t, \omega) + \zeta_{v,u-v}(t, \omega), u(t)) \end{aligned} \quad (16a)$$

$$\begin{aligned} b(t, \omega, v(\cdot), u(\cdot)) &:= \nabla_u L(t, \omega, z^v(t, \omega) + \zeta_{v,u-v}(t, \omega), u(t)) \end{aligned} \quad (16b)$$

$$\begin{aligned} c(t_f, \omega, v(\cdot), u(\cdot)) &:= \nabla_z G(t_f, \omega, z^v(t_f, \omega) + \zeta_{v,u-v}(t_f, \omega)) \end{aligned} \quad (16c)$$

the directional derivative $F'_{v(\cdot)+}$ can be represented by

$$\begin{aligned} & F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ &= E \left(\int_{t_0}^{t_f} \left(a(t, \omega, v(\cdot), u(\cdot)) \right)^T \zeta_{v,h}(t, \omega) \right. \\ &\quad + b(t, \omega, v(\cdot), u(\cdot))^T h(t) dt \\ &\quad \left. + c(t_f, \omega, v(\cdot), u(\cdot))^T \zeta_{v,h}(t_f, \omega) \right). \end{aligned} \quad (17a)$$

Integrating Equation (13a) over $[t_0, t_f]$, for each ω we get

$$\begin{aligned} \zeta_{v,h}(t_f, \omega) &= \int_{t_0}^{t_f} \dot{\zeta}_{v,h}(t, \omega) dt \\ &= \int_{t_0}^{t_f} \left(A(t, \omega, v(\cdot)) \zeta_{v,h}(t, \omega) \right. \\ &\quad \left. + B(t, \omega, v(\cdot)) h(t) \right) dt. \end{aligned} \quad (17b)$$

Putting Equation (17b) into Equation (17a), we find

$$\begin{aligned} & F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ &= E \left(\int_{t_0}^{t_f} \tilde{a}(t, \omega, v(\cdot), u(\cdot))^T \zeta_{v,h}(t, \omega) dt \right. \\ & \quad \left. + \int_{t_0}^{t_f} \tilde{b}(t, \omega, v(\cdot), u(\cdot))^T h(t) dt \right), \end{aligned} \quad (17c)$$

where

$$\begin{aligned} & \tilde{a}(t, \omega, v(\cdot), u(\cdot)) \\ &:= a(t, \omega, v(\cdot), u(\cdot)) + A(t, \omega, v(\cdot))^T \\ & \quad \times c(t_f, \omega, v(\cdot), u(\cdot)), \end{aligned} \quad (17d)$$

$$\begin{aligned} & \tilde{b}(t, \omega, v(\cdot), u(\cdot)) \\ &:= b(t, \omega, v(\cdot), u(\cdot)) + B(t, \omega, v(\cdot))^T \\ & \quad \times c(t_f, \omega, v(\cdot), u(\cdot)). \end{aligned} \quad (17e)$$

In order to transform the first integral in Equation (17c) into the form of the second integral in Equation (17c), we introduce the m -vector function

$$\lambda = \lambda^{v,u}(t, \omega)$$

defined by the following integral equation depending on the random parameter ω :

$$\begin{aligned} & \lambda(t) - A(t, \omega, v(\cdot))^T \int_t^{t_f} \lambda(s) ds \\ &= \tilde{a}(t, \omega, v(\cdot), u(\cdot)). \end{aligned} \quad (18)$$

Under the present assumptions, this *Volterra integral equation* has [11] a unique measurable solution $(t, \omega) \rightarrow \lambda^{v,u}(t, \omega)$. By means of Equation (18) we obtain

$$\begin{aligned} & \int_{t_0}^{t_f} \tilde{a}(t, \omega, v(\cdot), u(\cdot))^T \zeta_{v,h}(t, \omega) dt \\ &= \int_{t_0}^{t_f} \lambda(s)^T \left(\zeta_{v,h}(s, \omega) - \int_{t_0}^s A(t, \omega, v(\cdot)) \right. \\ & \quad \left. \times \zeta_{v,h}(t, \omega) dt \right) ds. \end{aligned} \quad (19a)$$

Now, using again the perturbation equations (13a) and (13b), from Equation (19a) we get

$$\begin{aligned} & \int_{t_0}^{t_f} \tilde{a}(t, \omega, v(\cdot), u(\cdot))^T \zeta_{v,h}(t, \omega) dt \\ &= \int_{t_0}^{t_f} \left(B(t, \omega, v(\cdot))^T \int_t^{t_f} \lambda(s) ds \right)^T h(t) dt. \end{aligned} \quad (19b)$$

Inserting Equation (19b) into Equation (17c), we have

$$\begin{aligned} & F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ &= E \left(\int_{t_0}^{t_f} \left(B(t, \omega, v(\cdot))^T \int_t^{t_f} \lambda(s) ds \right. \right. \\ & \quad \left. \left. + \tilde{b}(t, \omega, v(\cdot), u(\cdot)) \right)^T h(t) dt \right). \end{aligned} \quad (20)$$

By means of Equation (17d), the integral equation (18) may be written as

$$\begin{aligned} & \lambda(t) - A(t, \omega, v(\cdot))^T \left(c(t_f, \omega, v(\cdot), u(\cdot)) + \int_t^{t_f} \lambda(s) ds \right) \\ &= a(t, \omega, v(\cdot), u(\cdot)). \end{aligned} \quad (21)$$

According to Equation (21), we now define the m -vector function

$$\begin{aligned} y &= y^{v,u}(t, \omega) := c(t_f, \omega, v(\cdot), u(\cdot)) \\ & \quad + \int_t^{t_f} \lambda_{v,u}(s, \omega) ds. \end{aligned} \quad (22)$$

Obviously, $y = y^{v,u}(t, \omega)$ solves the system of differential equations

$$\begin{aligned} & \dot{y}(t) = -A(t, \omega, v(\cdot))^T y(t) - a(t, \omega, v(\cdot), u(\cdot)), \\ & t_0 \leq t \leq t_f, \end{aligned} \quad (23a)$$

$$y(t_f) = c(t_f, \omega, v(\cdot), u(\cdot)). \quad (23b)$$

Systems (23a) and (23b) are called the *adjoint differential equations* related to the perturbation equations (13a) and (13b).

Using Equation (22), from Equations (17e) and (20) we now obtain

$$\begin{aligned} F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ = E \left(\int_{t_0}^{t_f} \left(B(t, \omega, v(\cdot))^T y^{v,u}(t, \omega) \right. \right. \\ \left. \left. + b(t, \omega, v(\cdot), u(\cdot)) \right)^T h(t) dt \right). \end{aligned}$$

Summarizing the above transformations, we have the following result.

Theorem 2. *Suppose that the adjoint differential equation (23a), (23b) has a measurable solution $(\omega, t) \rightarrow y^{v,u}(t, \omega)$. Then,*

$$\begin{aligned} F'_{v(\cdot)+}(u(\cdot); h(\cdot)) \\ = \int_{t_0}^{t_f} E \left(B(t, \omega, v(\cdot))^T y^{v,u}(t, \omega) \right. \\ \left. + b(t, \omega, v(\cdot), u(\cdot)) \right)^T h(t) dt. \end{aligned} \quad (24)$$

Note that $F'_{v(\cdot)+}(u(\cdot); \cdot)$ is also the Gâteaux differential of $F_{v(\cdot)}$ at $u(\cdot)$ [10].

Note that in practice, the domain D of admissible controls is often given by

$$D = \{u(\cdot) \in U : u(t) \in D_t, t_0 \leq t \leq t_f\}, \quad (25)$$

where $D_t \subset \mathbb{R}^n$ is a given convex subset of $\mathbb{R}^n$ for each time t , $t_0 \leq t \leq t_f$.

STATIONARY CONTROLS

We now consider the construction of *stationary controls* of problem (6a)–(6d), hence, controls $\bar{u}(\cdot) \in D$ fulfill at least the necessary optimality condition $\bar{u}(\cdot) \in M(\bar{u}(\cdot))$, see Definition 2. Thus, stationary controls are candidates for stochastic optimal controls. For nonlinear control or optimization problems, finding stationary controls or stationary points is often the only possibility to get a useful approximate optimal solution.

Starting again with formula (24), by means of Equation (11), for an element $v(\cdot) \in D$ we have

$$\begin{aligned} F'_+(v(\cdot); h(\cdot)) &= F'_{v(\cdot)+}(v(\cdot); h(\cdot)) \\ &= \int_{t_0}^{t_f} E \left(B(t, \omega, v(\cdot))^T y^v(t, \omega) \right. \\ &\quad \left. + b(t, \omega, v(\cdot), v(\cdot)) \right)^T h(t) dt, \end{aligned} \quad (26a)$$

where

$$y^v(t, \omega) := y^{v,v}(t, \omega) \quad (26b)$$

fulfills, cf. Equations (23a) and (23b), the adjoint differential equation

$$\begin{aligned} \dot{y}(t, \omega) &= -A(t, \omega, v(\cdot))^T y(t, \omega) \\ &\quad - \nabla_z L(t, \omega, z^v(t, \omega), v(t)) \end{aligned} \quad (27a)$$

$$y(t_f, \omega) = \nabla_z G(t_f, \omega, z^v(t_f, \omega)); \quad (27b)$$

moreover, cf. Equations (13c) and (13d),

$$A(t, \omega, v(\cdot)) = D_z g(t, \omega, z^v(t, \omega), v(t)) \quad (27c)$$

$$B(t, \omega, v(\cdot)) = D_u g(t, \omega, z^v(t, \omega), v(t)) \quad (27d)$$

and

$$b(t, \omega, v(\cdot), v(\cdot)) = \nabla_u L(t, \omega, z^v(t, \omega), v(t)), \quad (27e)$$

where $z^v = z^v(t, \omega)$ solves the dynamic equation

$$\dot{z}(t, \omega) = g(t, \omega, z(t, \omega), v(t)), t_0 \leq t \leq t_f, \quad (27f)$$

$$z(t_0, \omega) = z_0(\omega). \quad (27g)$$

Adapting now the *Hamilton–Jacobi theory* for deterministic optimal control problems [6,20], to optimal control problems under stochastic uncertainty, we now

introduce the *stochastic Hamiltonian*:

$$H(t, \omega, z, y, u) := L(t, \omega, z, u) + y^T g(t, \omega, z, u) \quad (28a)$$

related to the basic control problems (6a)–(6d). From Equations (26a) and (26b), and Equations (27a)–(27g), for the directional derivative F'_+ we get then the representation

$$\begin{aligned} F'_{v(\cdot)+} (v(\cdot); h(\cdot)) &= F'_+ (v(\cdot); h(\cdot)) \\ &= \int_{t_0}^{t_f} E \nabla_u H(t, \omega, z^v(t, \omega), y^v(t, \omega), v(t))^T h(t) dt. \end{aligned} \quad (28b)$$

According to Definition 2, a stationary control of problem (5) is an element $\bar{u}(\cdot) \in D$ such that $\bar{u}(\cdot)$ is an optimal solution of the approximate problem (5) $_{\bar{u}(\cdot)}$. Using the characterization (10), under condition (11), a stationary control can now be characterized by

$$F'_+ (\bar{u}(\cdot); u(\cdot) - \bar{u}(\cdot)) \geq 0 \text{ for all } u(\cdot) \in D.$$

Thus, because of representation (28b), for stationary controls $\bar{u}(\cdot) \in D$ we have the characterization

$$\begin{aligned} &\int_{t_0}^{t_f} E \nabla_u H(t, \omega, z^{\bar{u}}(t, \omega), y^{\bar{u}}(t, \omega), \bar{u}(t))^T \\ &\quad \times (u(t) - \bar{u}(t)) dt \geq 0, u(\cdot) \in D. \end{aligned} \quad (29)$$

In order to show that condition (29) is related to an optimality principle, for given $w(\cdot) \in D$ we introduce the function

$$\begin{aligned} \bar{H}^w(u(\cdot)) &:= \\ &\int_{t_0}^{t_f} EH(t, \omega, z^w(t, \omega), y^w(t, \omega), u(t)) dt, \end{aligned} \quad (30a)$$

and we consider the variational problem

$$\min \bar{H}^w(u(\cdot)) \text{ s.t. } u(\cdot) \in D. \quad (30b)$$

If directional differentiation and integration/expectation in Equation (30a) may be

interchanged, which is assumed in the following, then Equation (29) is a necessary condition for

$$\bar{u}(\cdot) \in \operatorname{argmin}_{u(\cdot) \in D} \bar{H}^w(u(\cdot)). \quad (31)$$

Thus, corresponding to *Pontryagin's minimum principle* [6,10], we have this result.

Theorem 3. *Optimality principle. Suppose that a control $\bar{u}(\cdot) \in D$ fulfills problem (31). Then $\bar{u}(\cdot)$ is a stationary control of Equation (5).*

Canonical System of Differential Equations for Stationary Controls

Assume again that the feasible domain D is given by Equation (25). In order to solve the optimization problems (30a) and (30b), we next replace $z^{\bar{u}}(\cdot, \omega), y^{\bar{u}}(\cdot, \omega)$ by measurable functions $\zeta(\cdot), \eta(\cdot)$ on $(\Omega, \mathcal{A}, P)$. Then, minimizing under the integral sign in Equation (30a), we obtain the finite-dimensional *stochastic optimization problem*

$$\min EH(t, \omega, \zeta(\omega), \eta(\omega), u) \text{ s.t. } u \in D_t \quad (P)_{\zeta, \eta}^t$$

for each $t, t_0 \leq t \leq t_f$. For arbitrary measurable functions $\zeta(\cdot), \eta(\cdot)$ on $(\Omega, \mathcal{A}, P)$, such that the expectation in $(P)_{\zeta, \eta}^t$ exists and is finite, let

$$\tilde{u}^* = \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot)), t_0 \leq t \leq t_f,$$

denote a solution of Equation $(P)_{\zeta, \eta}^t$. As a basic tool in the *Hamilton–Jacobi theory* [6,20], we use this important notion.

Definition 3. The function $\tilde{u}^* = \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot)), t_0 \leq t \leq t_f$, is called a **H-minimal control** of problem (6a)–(6d).

For a given H -minimal control $\tilde{u}^* = \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot))$, which can be interpreted as a *stochastic optimal control law*, we consider the related *canonical (Hamiltonian) two-point boundary value problem with*

random parameters:

$$\dot{z}(t, \omega) = g\left(t, \omega, z(t, \omega), \tilde{u}^*\left(t, z(t, \cdot), y(t, \cdot)\right)\right), \quad t_0 \leq t \leq t_f \quad (32a)$$

$$z(t_0, \omega) = z_0(\omega) \quad (32b)$$

$$\begin{aligned} \dot{y}(t, \omega) = & -D_z g\left(t, \omega, z(t, \omega), \tilde{u}^*\left(t, z(t, \cdot), y(t, \cdot)\right)\right)^T y(t, \omega) \\ & -\nabla_z L\left(t, \omega, z(t, \omega), \tilde{u}^*\left(t, z(t, \cdot), y(t, \cdot)\right)\right), \quad t_0 \leq t \leq t_f \end{aligned} \quad (32c)$$

$$y(t_f, \omega) = \nabla_z G\left(t_f, \omega, z(t_f, \omega)\right). \quad (32d)$$

Remark 5. In case of a discrete distribution $\Omega = \{\omega_1, \dots, \omega_\varrho\}$, $P(\omega = \omega_j) = \alpha_j, j = 1, \dots, \varrho$, for the H -minimal control we have

$$\tilde{u}^* = \tilde{u}^*\left(t, z(t, \omega_1), \dots, z(t, \omega_\varrho), y(t, \omega_1), \dots, y(t, \omega_\varrho)\right).$$

Thus, system (32a)–(32d) is then an ordinary two-point boundary value problems for the 2ϱ unknown functions $z = z(t, \omega_j), y = y(t, \omega_j), j = 1, \dots, \varrho$.

Let $(z^*, y^*) = (z^*(t, \omega), y^*(t, \omega)), t_0 \leq t \leq t_f, \omega \in (\Omega, \mathcal{A}, P)$, denote the unique measurable solution of system (32a)–(32d) and define the control

$$u^*(t) := \tilde{u}^*\left(t, z^*(t, \cdot), y^*(t, \cdot)\right), t_0 \leq t \leq t_f. \quad (33)$$

Owing to Equations (13e) and (26b), and (27a) and (27b), for all $\omega \in (\Omega, \mathcal{A}, P)$ we have

$$z^*(t, \omega) = z^{u^*}(t, \omega), t_0 \leq t \leq t_f, \quad (34a)$$

$$y^*(t, \omega) = y^{u^*}(t, \omega), t_0 \leq t \leq t_f \quad (34b)$$

and therefore

$$u^*(t) = \tilde{u}^*\left(t, z^{u^*}(t, \cdot), y^{u^*}(t, \cdot)\right), t_0 \leq t \leq t_f. \quad (34c)$$

Assuming that

$$u^*(\cdot) \in U \text{ (and therefore } u^*(\cdot) \in D), \quad (35)$$

we get this result.

Theorem 4. Suppose that the canonical system (32a)–(32d) has a unique measurable solution $(z^*, y^*) = (z^*(t, \omega), y^*(t, \omega))$, and define $u^*(\cdot)$ by Equation (33) with a H -minimal control $\tilde{u}^* = \tilde{u}^*(t, \zeta, \eta)$. If $u^*(\cdot) \in U$, then $u^*(\cdot)$ is a stationary control; hence, it fulfills the necessary optimality conditions of the optimal control problem (6a)–(6d).

Proof. According to the construction of (z^*, y^*, u^*) , the control $u^*(\cdot) \in D$ minimizes $\overline{H}^{u^*}(u(\cdot))$ on D . Hence,

$$u^*(\cdot) \in \operatorname{argmin}_{u(\cdot) \in D} \overline{H}^{u^*}(u(\cdot)).$$

Theorem 3 yields then that $u^*(\cdot)$ is a stationary control.

STOCHASTIC PROGRAMMING METHODS

Besides the methods for the calculation of expectations and/or solutions of (finite-dimensional) stochastic programming problems considered in this article, that is, discretization and Taylor expansion methods, there are further well-known methods, for example, based on finite-difference approximation and stochastic quasigradient methods, stochastic linearization procedures, see Ref. 21. However, in the present case not a single stochastic program has to be solved once, but H -minimal controls $\tilde{u}^*$, hence, control laws (functions). Thus, at each time instant t and for certain random variables $\zeta(\omega), \eta(\omega)$, stochastic optimal control laws must be determined (i) as solutions, see the section titled “Canonical System of Differential Equations for Stationary Controls”, of

$$\min EH\left(t, \omega, \zeta(\omega), \eta(\omega), u\right) \text{ s.t. } u \in D_t,$$

and (ii) inserted into the Hamiltonian two-point boundary value problem. Consequently, the solution method for finding $\tilde{u}^*$ does not allow many iterations as needed, for example, in case of stochastic gradient methods, based on *stochastic gradients*

$$\widehat{\nabla_u H}^{(k)} := \nabla_u H(t, \omega^{(k)}, \zeta(\omega^{(k)}), \eta(\omega^{(k)}), u^{(k)})$$

at certain iteration points $u^{(k)}$. Here, ∇_u denotes the gradient with respect to u , and $\omega^{(k)}, k = 1, 2, \dots$, is a series of stochastically independent realizations of the random element ω . Moreover, in order to take into account the constraint $u \in D_t$, projection-type stochastic gradient-type methods must be applied. In addition, it is known that the convergence rate of stochastic gradient procedures may be very small. For a more detailed consideration of stochastic approximation, especially stochastic gradient methods, including hybrid methods, see Ref. 7.

On the other hand, using discretization techniques as well as Taylor expansion methods, the control problem under stochastic uncertainty is reduced to a deterministic control problem involving approximate trajectories corresponding to the applied approximation method. Of course, this presupposes that a moderate number of appropriate realizations of the random element ω , of the random parameter vector $\theta(\omega)$, respectively, can be found for the discretization method; the moments of the random elements, random parameters of third and higher order are small in case of the Taylor expansion method.

Stochastic Programs and Recourse Cost Models

The method developed in the sections titled “Computation of Directional Derivatives” and “Stationary Controls” is considered now in the following case.

Let the function g of the dynamic equation (1a) be affine-linear with respect to the control input u , and assume that the cost function L along the trajectory is separable (additive) with respect to state and control,

hence,

$$g(t, \omega, z, u) = \hat{g}(t, \omega, z) + \hat{B}(t, \omega, z)u \quad (36a)$$

$$L(t, \omega, z, u) = \hat{L}(t, \omega, z) + Q(t, \omega, u). \quad (36b)$$

The stochastic optimization problem $(P)_{\xi, \eta}^t$ is then equivalent to the *stochastic program* [7, 14]

$$\min_{u \in D_t} E \left(\left(\hat{B}(t, \omega, \zeta(\omega))^T \eta(\omega) \right)^T u + Q(t, \omega, u) \right). \quad (37)$$

The important properties of this problem and its solutions can be obtained in the following situations:

- (a) If $Q = Q(t, \omega, u)$ is (strictly) convex with respect to u , then Equation (37) is a (strictly) convex program.
- (b) If $B(t, \omega, z)$ does not depend on z , on (ω, z) , respectively, then

$$\begin{aligned} \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot)) &= \tilde{u}^*(t, \eta(\cdot)), \\ \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot)) &= \tilde{u}^*(t, E\eta(\omega)). \end{aligned}$$

- (c) If $Q(t, \omega, u) = \frac{1}{2}u^T u$ and $D_t = \mathbb{R}^n$, then

$$\tilde{u}^*(t, \zeta(\cdot), \eta(\cdot)) = -E\hat{B}(t, \omega, \zeta(\omega))^T \eta(\omega).$$

- (d) If the cost function $Q = Q(t, \omega, u)$ is strictly convex in u for each $(t, \omega) \in [t_0, t_f] \times \Omega$ a.s., and the admissible sets D_t , $t_0 \leq t \leq t_f$, are compact, then the program (37) has a unique optimal solution. Hence, the H -minimal control $\tilde{u}^* = \tilde{u}^*(t, \zeta(\cdot), \eta(\cdot))$ is determined uniquely.
- (e) For a discrete probability distribution $\Omega = \{\omega_1, \dots, \omega_\varrho\}$, $P(\omega = \omega_j) = \alpha_j, j = 1, \dots, \varrho, \sum_{j=1}^{\varrho} \alpha_j = 1$, Equation (37) is reduced to the ordinary deterministic parameter optimization problem

$$\begin{aligned} \min_{u \in D_t} \sum_{j=1}^{\varrho} \alpha_j \left(\hat{B}(t, \omega_j, \zeta(\omega_j))^T \eta(\omega_j) \right)^T u \\ + \sum_{j=1}^{\varrho} \alpha_j Q(t, \omega_j, u) \end{aligned} \quad (37')$$

depending on the parameters $(\omega_j, \zeta(\omega_j), \eta(\omega_j))$ and probabilities α_j , $j = 1, \dots, \varrho$.

- (f) *Recourse cost models* Stochastic programs of the above type (37) are well studied, especially for *recourse cost models* [14, 22] related to compensation of violations of stochastic control constraints, hence,

$$Q(t, \omega, u) := p_t(T(t, \omega)u - b(t, \omega)). \quad (38a)$$

Here, $b : [t_0, t_f] \times \Omega \rightarrow \mathbb{R}^q$, $T : [t_0, t_f] \times \Omega \rightarrow \mathbb{R}^{q \times n}$ are vector-, matrix-valued measurable functions, and $p_t : \mathbb{R}^q \rightarrow \mathbb{R}$ is a convex or sublinear function [14]. We may then interpret $Q(t, \omega, u)$ as the loss resulting from compensating the violation $\delta = T(t, \omega)u - b(t, \omega) \neq 0, \neq 0$, respectively, of stochastic linear equality or inequality control constraints

$$T(t, \omega)u = b(t, \omega), T(t, \omega)u \leq b(t, \omega), \\ t_0 \leq t \leq t_f,$$

after revealing the uncertain parameters. One of great importance is the case that $b(t, \cdot)$, $T(t, \cdot)$ are stable distributed stochastic processes [23]. The objective function of Equation (37) has then the form

$$\phi(u) = \bar{c}(t)^T u + E p_t(T(t, \omega)u - b(t, \omega)), \\ u \in \mathbb{R}^n, \quad (38b)$$

where $\bar{c}(t)$ is defined by

$$\bar{c}(t) = E \hat{B}(t, \omega, \gamma(\omega))^T \eta(\omega). \quad (38c)$$

On the basis of the *stochastic dominance* concept, for problems with stable distributed processes $(T(t, \omega), b(t, \omega))$ several important properties, such as the construction of feasible descent directions, of stochastic programs having an objective function of the type (38b) are shown in Ref. 14.

Computation of Expectations by means of Taylor Expansion

Corresponding to the assumptions in the section titled “Parametric Representation of the Random Differential Equation”, we suppose here the following parametric representation of the functions under consideration:

$$g(t, w, z, u) = \tilde{g}(t, \theta, z, u) \quad (39a)$$

$$z_0(\omega) = \tilde{z}_0(\theta) \quad (39b)$$

$$L(t, \omega, z, u) = \tilde{L}(t, \theta, z, u) \quad (39c)$$

$$G(t, \omega, z) = \tilde{G}(t, \theta, z) \quad (39d)$$

with a time-independent r -vector

$$\theta = \theta(\omega), \omega \in (\Omega, \mathcal{A}, P), \quad (39e)$$

of random model and environmental parameters including initial values. Furthermore, we assume that $\tilde{g}, \tilde{z}_0, \tilde{L}, \tilde{G}$ are sufficiently smooth functions of the indicated variables. For simplification of notation we omit the symbol “ $\sim$ ”.

Again, for simplification, the conditional expectation $E(\dots | \mathcal{A}_{t_0})$, given the information $\mathcal{A}_{t_0}$ up to the considered starting or reference time t_0 is denoted by “ E ”. Thus, let

$$\bar{\theta} := E\theta(\omega) = E(\theta(\omega) | \mathcal{A}_{t_0}) \quad (40a)$$

denote the conditional expectation of the random vector $\theta(\omega)$ given the information $\mathcal{A}_{t_0}$ at time point t_0 . Taking into account the properties of the solution

$$z = z(t, \theta) = S(z_0(\theta), \theta, u(\cdot))(t), t \geq t_0, \quad (40b)$$

of the dynamic equations (3a)–(3d), see Lemma 1 and Lemma 2, the expectations arising in the objective function (6a) can be computed approximately by means of Taylor expansion with respect to θ at $\bar{\theta}$.

According to Equations (39a)–(39e) we have the parametric representation of $z(t, \cdot), y(t, \cdot)$:

$$z(t, \omega) = z(t, \theta(\omega)), y = y(t, \theta(\omega)). \quad (41)$$

We consider then the Taylor expansions

$$\begin{aligned} z(t, \omega) &= z(t, \theta(\omega)) \\ &= z(t, \bar{\theta}) + z_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}) + \dots \end{aligned} \quad (42a)$$

$$\begin{aligned} y(t, \omega) &= y(t, \theta(\omega)) \\ &= y(t, \bar{\theta}) + y_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}) + \dots \end{aligned} \quad (42b)$$

Deleting second- and higher-order terms, we have to determine the functions

$$z = z(t, \bar{\theta}), y = y(t, \bar{\theta}), t_0 \leq t \leq t_f \quad (43a)$$

$$z_\theta = z_\theta(t, \bar{\theta}), y_\theta = y_\theta(t, \bar{\theta}), t_0 \leq t \leq t_f, \quad (43b)$$

with the Jacobians $z_\theta(t, \bar{\theta}) := D_\theta z(t, \bar{\theta})$ and $y_\theta(t, \bar{\theta}) := D_\theta y(t, \bar{\theta})$.

Using this expansion, the stochastic optimization problem $(P)_{\zeta, \eta}^t$ with $\zeta := z(t, \theta(\cdot))$, $\eta := y(t, \theta(\cdot))$ can be approximated by

$$\begin{aligned} \min_{u \in D_t} EH \left(t, \theta(\omega), z(t, \bar{\theta}) + z_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}), \right. \\ \left. y(t, \bar{\theta}) + y_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}), u \right). \end{aligned} \quad (44)$$

Thus, the resulting approximate H -minimal control

$$\tilde{u}^* = \tilde{u}^*(t, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), y(t, \bar{\theta}), y_\theta(t, \bar{\theta})) \quad (45)$$

depends on the unknown vector and matrix functions stated in Equations (43a) and (43b).

Describing random parameter variations by means of a certain finite-dimensional random parameter vector $\theta = \theta(\omega)$, a two-point boundary value problem for the unknown functions stated in Equations (43a) and (43b) can be then obtained from Equations (32a)–(32d), as is described in more detail in the following, by (i) putting $\theta = \bar{\theta}$ and by (ii) differentiating with respect to θ and then putting $\theta = \bar{\theta}$.

Computation of Trajectories and Sensitivities for $\theta = \bar{\theta}$.

1. Trajectory $z = z(t, \omega) = z(t, \theta(\omega))$.

According to the first-order Taylor approximation (42a) of $z = z(t, \theta)$

at $\theta = \bar{\theta}$, we still have to compute the trajectory $t \rightarrow z(t, \bar{\theta}), t \geq t_0$, related to the mean parameter vector $\theta = \bar{\theta}$ and the sensitivities $t \rightarrow \frac{\partial z}{\partial \theta_i}(t, \bar{\theta}), i = 1, \dots, r, t \geq t_0$, of the state $z = z(t, \theta)$ with respect to the parameters $\theta_i, i = 1, \dots, r$, at $\theta = \bar{\theta}$. On the basis of Equations (3a) and (3b), in case of Equations (39a)–(39d) for $z = z(t, \bar{\theta})$, we have the system of differential equations

$$\dot{z}(t, \bar{\theta}) = g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) t \geq t_0, \quad (46a)$$

$$z(t_0, \bar{\theta}) = z_0(\bar{\theta}). \quad (46b)$$

Moreover, assuming that differentiation with respect to $\theta_i, i = 1, \dots, r$, and integration with respect to time t can be interchanged, see Lemma 1, from Equation (3c) we obtain the following system of linear perturbation differential equations for the Jacobian $z_\theta(t, \bar{\theta}) = \left(\frac{\partial z}{\partial \theta_1}(t, \bar{\theta}), \frac{\partial z}{\partial \theta_2}(t, \bar{\theta}), \dots, \frac{\partial z}{\partial \theta_r}(t, \bar{\theta}) \right), t \geq t_0$:

$$\begin{aligned} \frac{d}{dt} (z_\theta(t, \bar{\theta})) &= D_z g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) z_\theta(t, \bar{\theta}) \\ &\quad + D_\theta g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)), \\ t &\geq t_0, \end{aligned} \quad (47a)$$

$$z_\theta(t_0, \bar{\theta}) = z_{0\theta}(\bar{\theta}). \quad (47b)$$

Note. Equations (47a) and (47b) are closely related to the perturbation equation (13a), (13b) for representing the derivative z'' of z with respect to the control u .

2. Adjoint trajectory $y = y(t, \omega) = y(t, \theta(\omega))$.

The adjoint trajectory $y = y(t, \theta)$ is defined by the system of linear differential equation systems (27a) and (27b) with $v(\cdot) = u(\cdot)$. Hence, using the parameter representations (39a)–(39e), for $y = y(t, \theta)$, we have the

terminal value problem

$$\begin{aligned} \dot{y}(t, \theta) = & -D_z g(t, \theta, z(t, \theta), u(t))^T y(t, \theta) \\ & - \nabla_z L(t, \theta, z(t, \theta), u(t)) \end{aligned} \quad (48a)$$

$$y(t_f, \theta) = \nabla_z G(t_f, \theta, z(t_f, \theta)). \quad (48b)$$

Putting $\theta := \bar{\theta}$, from Equations (48a) and (48b) we obtain a terminal value problem for $y = y(t, \bar{\theta})$. Furthermore, corresponding to the derivation of a system of first-order ordinary differential equations for the Jacobian $z_\theta(t, \bar{\theta})$, a system of first-order differential equations for the Jacobian $y_\theta(t, \bar{\theta})$ can be obtained, by differentiation of Equations (48a) and (48b) with respect to θ at $\theta = \bar{\theta}$.

Remark 6. The differentiation of Equations (48a) and (48b) with respect to θ is especially simple if the Jacobian $D_z g = D_z g(t, u(t))$ of g with respect to z is independent of $(\theta, z(t, \theta))$ (see the section titled “Optimal Regulator Design for Dynamic Systems Under Stochastic Uncertainty”).

Deterministic Substitute Optimal Control Problem

Instead of solving the optimal control problem (6a)–(6d) under stochastic uncertainty, using the stochastic Hamiltonian H as described in the sections titled “Computation of Directional Derivatives” and “Stationary Controls”, we can replace this stochastic control problem *directly* by an *approximate deterministic substitute control problem* by computation of the expectation in the objective function (6a) using Taylor expansion with respect to the random parameter vector $\theta = \theta(\omega)$ at $\bar{\theta}$. For this purpose we need the (approximate) Hessians of the cost functions along the trajectory, at the terminal point, respectively,

$$\theta \rightarrow L(t, \theta, z(t, \theta), u), \theta \rightarrow G(t, \theta, z(t, \theta))$$

at $\theta = \bar{\theta}$.

Retaining only first-order derivatives of $z = z(t, \theta)$ with respect to θ , the approximate Hessian Q_L of $\theta \rightarrow L(t, \theta, z(t, \theta), u)$ at $\theta = \bar{\theta}$ is given [7], by

$$\begin{aligned} Q_L(t, \bar{\theta}, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), u(t)) \\ := \nabla_\theta^2 L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) \\ + z_\theta(t, \bar{\theta})^T \nabla_{\theta z} L(t, \bar{\theta}, z(t, \bar{\theta}), u(t))^T \\ + \nabla_{\theta z} L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) z_\theta(t, \bar{\theta}) \\ + z_\theta(t, \bar{\theta})^T \nabla_z^2 L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) z_\theta(t, \bar{\theta}). \end{aligned} \quad (49)$$

Here, $\nabla_\theta L, \nabla_z L$ denotes the gradient of L with respect to θ, z , respectively, z_θ is the Jacobian of $z = z(t, \theta)$ with respect to θ , and $\nabla_\theta^2 L, \nabla_z^2 L$, respectively, denotes the Hessian of L with respect to θ, z .

Thus, for the expected costs $EL = E(L|\mathcal{A}_{t_0})$, with Equation (49) we obtain the expansion

$$\begin{aligned} EL(t, \theta(\omega), z(t, \theta(\omega)), u(t)) \\ = L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) + \frac{1}{2} E(\theta(\omega) - \bar{\theta})^T \\ \times Q_L(t, \bar{\theta}, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), u(t)) \\ \times (\theta(\omega) - \bar{\theta}) + \dots \\ = L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) \\ + \frac{1}{2} \text{tr} Q_L(t, \bar{\theta}, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), u(t)) \\ \times \text{cov}(\theta(\cdot)) + \dots \end{aligned} \quad (50)$$

In order to evaluate formula (50), besides the distributional parameters $\bar{\theta}$ and $\text{cov}(\theta(\cdot)) = E(\theta(\omega) - \bar{\theta})(\theta(\omega) - \bar{\theta})^T$, we need the functions $z = z(t, \bar{\theta})$ and $z_\theta = z_\theta(t, \bar{\theta})$. However, $z = z(t, \bar{\theta}), t \geq t_0$, is the solution of the dynamic equations (3a)–(3c) for $\theta = \bar{\theta}$. Moreover, a system of differential equations for the derivatives $\frac{\partial z_k}{\partial \theta_i} = \frac{\partial z_k}{\partial \theta_i}(t, \bar{\theta}), t \geq t_0$,

is obtained as described in the section titled “Computation of Trajectories and Sensitivities for $\theta = \bar{\theta}$ ”.

Defining the approximate Hessian Q_G of $\theta \rightarrow G(t, \theta, z(t, \theta))$ at $\theta = \bar{\theta}$ as in case of Q_L , see Equation (49), for $EG = E(G|A_{t_0})$ we get the expansion

$$\begin{aligned} EG(t_f, \theta(\omega), z(t_f, \theta(\omega))) &= G(t_f, \bar{\theta}, z(t_f, \bar{\theta})) \\ &+ \frac{1}{2} \text{tr} Q_G(t_f, \bar{\theta}, z(t_f, \bar{\theta}), z_{\theta}(t_f, \bar{\theta})) \text{cov}(\theta(\cdot)) + \dots \end{aligned} \quad (51)$$

For the stochastic control problem (6a)–(6d) we then obtain the following approximation.

Theorem 5. *Suppose that differentiation with respect to the parameters $\theta_i, i = 1, \dots, r$, and integration with respect to time t can be interchanged in Equation (3c). Retaining only first-order derivatives of $z = z(t, \theta)$ with respect to θ , problem (6a)–(6d) can be approximated by the ordinary deterministic optimal control problem:*

$$\begin{aligned} \min \int_{t_0}^{t_f} &\left\{ L(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) \right. \\ &+ \frac{1}{2} \text{tr} Q_L(t, \bar{\theta}, z(t, \bar{\theta}), z_{\theta}(t, \bar{\theta}), u(t)) \text{cov}(\theta(\cdot)) \Big\} dt \\ &+ G(t_f, \bar{\theta}, z(t_f, \bar{\theta})) \\ &+ \frac{1}{2} \text{tr} Q_G(t_f, \bar{\theta}, z(t_f, \bar{\theta}), z_{\theta}(t_f, \bar{\theta})) \text{cov}(\theta(\cdot)) \end{aligned} \quad (52a)$$

s.t.

$$\dot{z}(t, \bar{\theta}) = g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)), t \geq t_0, \quad (52b)$$

$$z(t_0, \bar{\theta}) = z_0(\bar{\theta}) \quad (52c)$$

$$\begin{aligned} \frac{d}{dt}(z_{\theta}(t, \bar{\theta})) &= D_z g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)) z_{\theta}(t, \bar{\theta}) \\ &+ D_{\theta} g(t, \bar{\theta}, z(t, \bar{\theta}), u(t)), t \geq t_0, \end{aligned} \quad (52d)$$

$$z_{\theta}(t_0, \bar{\theta}) = z_{0\theta}(\bar{\theta}) \quad (52e)$$

$$u(\cdot) \in D. \quad (52f)$$

Note. According to previous remarks, we have

$$\begin{aligned} \bar{\theta} = \bar{\theta}^{(t_0)} &:= E(\theta(\omega) | A_{t_0}) \\ \text{cov}(\theta(\cdot)) &= \text{cov}^{(t_0)}(\theta(\cdot)) \\ &:= E\left((\theta(\omega) - \bar{\theta}^{(t_0)}) (\theta(\omega) - \bar{\theta}^{(t_0)})^T | A_{t_0}\right). \end{aligned}$$

Remark 7. The deterministic control problem (52a)–(52f) can be solved, of course, also by applying the Hamilton–Jacobi theory to this deterministic problem. Comparing then the corresponding two-point boundary value problem related to Equations (52a)–(52f) with the two-point boundary value problem resulting from the two-point boundary problem (32a)–(32d) with random parameters after applying Taylor expansion methods with respect to θ at $\bar{\theta}$, as described in the sections titled “Computation of Expectations by means of Taylor Expansion” and “Computation of Trajectories and Sensitivities for $\theta = \bar{\theta}$ ”, a close relationship of these two approaches is revealed.

OPTIMAL REGULATOR DESIGN FOR DYNAMIC SYSTEMS UNDER STOCHASTIC UNCERTAINTY

On the basis of a prescribed *optimal reference trajectory* of a dynamic system under stochastic uncertainty, the problem is to keep the system on this trajectory as exactly as possible by means of control corrections obtained by applying a stochastic optimal feedback control law $\varphi = \varphi(t, \Delta q, \Delta \dot{q})$, hence, a PD controller, where $\Delta q, \Delta \dot{q}$ denote the tracking error and its time derivative [12,24,25].

Taylor expansion of the feedback function φ at $\Delta q = 0, \Delta \dot{q} = 0$, retaining only linear terms, and using the additional condition $\varphi(t, 0, 0) = 0$ we get the approximation:

$$\begin{aligned} \varphi(t, \Delta q(t), \Delta \dot{q}(t)) &\approx D_{\Delta q} \varphi(t, 0, 0) \Delta q(t) \\ &+ D_{\Delta \dot{q}} \varphi(t, 0, 0) \Delta \dot{q}(t). \end{aligned} \quad (53)$$

Linearizing the dynamic equation of the underlying dynamic system around the reference trajectory, its first and second time derivative as well as around the expectation of the stochastic dynamic parameters $p_D(\omega)$, and using the linearized control law stated in Equation (53), for the tracking error Δq we get the following system of linear differential equations

$$\begin{aligned} &Y(t) \Delta p_D(\omega) + K(t) \Delta q(t) \\ &+ D(t) \Delta \dot{q}(t) + M(t) \Delta \ddot{q}(t) \\ &= D_{\Delta q} \varphi(t, 0, 0) \Delta q(t) + D_{\Delta \dot{q}} \varphi(t, 0, 0) \Delta \dot{q}(t), \\ &t_0 \leq t \leq t_f, \end{aligned} \quad (54a)$$

with certain deterministic matrices $Y(t), K(t), D(t), M(t)$ depending on the optimal reference trajectory [12]. Moreover, $\Delta p_D(\omega)$ denotes the deviation of the vector of dynamic parameters from its expectation. The above equation can be rewritten as

$$\begin{aligned} &M(t) \Delta \ddot{q}(t) + (K(t) - D_{\Delta q} \varphi(t, 0, 0)) \Delta q(t) \\ &+ (D(t) - D_{\Delta \dot{q}} \varphi(t, 0, 0)) \Delta \dot{q}(t), \\ &= -Y(t) \Delta p_D(\omega). \end{aligned} \quad (54b)$$

In many applications M is always regular. Hence, defining

$$K_p(t) := M(t)^{-1} (K(t) - D_{\Delta q} \varphi(t, 0, 0)), \quad (54c)$$

$$K_d(t) := M(t)^{-1} (D(t) - D_{\Delta \dot{q}} \varphi(t, 0, 0)), \quad (54d)$$

from Equations (54b)–(54d) we get

$$\begin{aligned} \Delta \ddot{q}(t) &= -K_p(t) \Delta q(t) - K_d(t) \Delta \dot{q}(t) \\ &- M(t)^{-1} Y(t) \Delta p_D(\omega). \end{aligned} \quad (55a)$$

By introducing the state variable

$$\Delta z(t) := \begin{pmatrix} \Delta q(t) \\ \Delta \dot{q}(t) \end{pmatrix}, \quad (55b)$$

the second order differential equation (55a) will be transformed into a system of first-order differential equations

$$\begin{aligned} \Delta \dot{z}(t, \omega) &= \begin{pmatrix} \Delta \dot{q} \\ -K_p(t) \Delta q(t) - K_d(t) \Delta \dot{q}(t) \\ -M(t)^{-1} Y(t) \Delta p_D(\omega) \end{pmatrix} \\ &= \begin{pmatrix} 0 & I \\ -K_p(t) & -K_d(t) \end{pmatrix} \Delta z(t, \omega) \\ &+ \begin{pmatrix} 0 \\ -M(t)^{-1} Y(t) \Delta p_D(\omega) \end{pmatrix}. \end{aligned} \quad (55c)$$

The above Equation (55c) can also be represented by

$$\Delta \dot{z}(t, \omega) = A(V(t)) \Delta z(t, \omega) + a(t, \Delta p_D(\omega)), \quad (56a)$$

where

$$A(V(t)) := \begin{pmatrix} 0 & I \\ -K_p(t) & -K_d(t) \end{pmatrix} \quad (56b)$$

$$a(t, \Delta p_D) := \begin{pmatrix} 0 \\ -M^{(0)}(t)^{-1} Y^{(0)}(t) \end{pmatrix} \Delta p_D(\omega), \quad (56c)$$

and

$$V(t) := (K_p(t), K_d(t)). \quad (56d)$$

The performance of the feedback control is given by means of the quadratic cost functions (4d) and (4e)

$$L(t, \omega, \Delta z, \varphi) := \Delta z^T Q(\omega) \Delta z + \varphi^T R(\omega) \varphi, \quad (57a)$$

where the feedback law φ is approximated (PD controller) according to Equation (53). Moreover, in the present application we have a zero terminal cost function

$$G(z) := 0. \quad (57b)$$

According to Equations (54c) and (54d), there is a 1-1 relationship between the

unknown derivatives $D_{\Delta q}\varphi(t, 0, 0), D_{\Delta \dot{q}}\varphi(t, 0, 0)$ of the feedback control law φ and the regulator parameters contained in the matrices $K_p(t), K_d(t)$. Hence, in case of regulator optimization, the unknown input function $u = u(t)$ is the *the matrix (56d) of unknown, time-dependent regulator parameters*, thus,

$$“u(t)” = V(t) := (K_p(t), K_d(t)). \quad (58a)$$

With Equations (54c) and (54d), the performance function of the regulator optimization problem is then represented, cf. Equations (57a) and (57b), by

$$L(t, \omega, \Delta z, \varphi) = \Delta z^T \tilde{Q}(t, V(t)) \Delta z, \quad (58b)$$

where

$$\tilde{Q}(t, V(t)) := Q + B(t, V(t))^T R B(t, V(t)), \quad (58c)$$

$$B(t, V(t)) := (K(t), D(t)) - M(t)V(t). \quad (58d)$$

Remark 8. Note that in the present case $u, q, \dot{q}, z, \ddot{q}, \theta$ are replaced by the standard notation $V, \Delta q, \Delta \dot{q}, \Delta z, \Delta \ddot{q}, \Delta p_D$ in regulator theory.

According to the approximate computation of expectations developed in the section titled “Computation of Expectations by means of Taylor Expansion”, cf. Equations (42a) and (42b); (43a and (43b); (44); and (45), for finding now a H -minimal control

$$\tilde{V}^* = \tilde{V}^*(t, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), y(t, \bar{\theta}), y_\theta(t, \bar{\theta})) \quad (59)$$

we have to solve the minimization problem

$$\min_{V \in D_t} EH \left(t, \theta(\omega), z(t, \bar{\theta}) + z_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}), y(t, \bar{\theta}) + y_\theta(t, \bar{\theta})(\theta(\omega) - \bar{\theta}), V \right). \quad (60)$$

Here, the Hamilton function reads, cf. Equations (56a)–(56d); Equations (57a) and (57b),

$$H(t, \Delta p_D, \Delta z, y, V) := \Delta z^T \tilde{Q}(t, V(t)) \Delta z + y^T (A(V(t)) \Delta z + a(t, \Delta p_D)), \quad (61a)$$

where

$$\theta(\omega) := \Delta p_D = p_D(\omega) - \bar{p}_D \quad (61b)$$

denotes the deviation of the vector $p_D(\omega)$ of dynamic parameters from its expectation $\bar{p}_D$. According to the linear-quadratic structure of H in the present case, the expectation in Equation (60) can then be determined explicitly in terms of the expectation $\bar{\theta}$ and covariance matrix $cov(\theta(\cdot))$ of the random parameter vector $\theta(\omega) := \Delta p_D(\omega)$. Moreover, depending on the concrete regulator problem, the solution of problem (60) at each time point t is determined (partly) analytically or by using numerical optimization procedures.

Thus, for finding the functions

$$t \rightarrow (z(t, \bar{\theta}), y(t, \bar{\theta}), z_\theta(t, \bar{\theta}), y_\theta(t, \bar{\theta})), t_0 \leq t \leq t_f,$$

needed in the Taylor expansions (42a) and (42b); (43a) and (43b), we have, see sections titled “Stationary Controls” and “Stochastic Programming Methods” and Remark 6, the following two-point boundary value problem:

Theorem 6. Let $\theta(\omega) = \Delta p_D(\omega)$ denote the random parameter vector of the regulator optimization problem. Assuming the existence of the derivatives under consideration, for the functions $z = z(t, \bar{\theta}), y = y(t, \bar{\theta})$ and $z_\theta = z_\theta(t, \bar{\theta}), y_\theta = y_\theta(t, \bar{\theta})$ we have the two-point boundary value problem

$$\dot{z}(t, \bar{\theta}) = A(\tilde{V}^*)z(t, \bar{\theta}) + a(t, \bar{\theta}), t_0 \leq t \leq t_f, \quad (62a)$$

$$z(t_0, \bar{\theta}) = z_0(\bar{\theta}) \quad (62b)$$

$$\dot{y}(t, \bar{\theta}) = -A(\tilde{V}^*)^T y(t, \bar{\theta}) - 2\tilde{Q}(t, \tilde{V}^*)z(t, \bar{\theta}) \quad (62c)$$

$$y(t_f, \bar{\theta}) = 0 \quad (62d)$$

$$\dot{z}_\theta(t, \bar{\theta}) = A(\tilde{V}^*)z_\theta(t, \bar{\theta}) + a_\theta(t, \bar{\theta}) \quad (62e)$$

$$z_\theta(t_0, \bar{\theta}) = z_{0\theta}(\bar{\theta}) \quad (62f)$$

$$\dot{y}_\theta(t, \bar{\theta}) = -A(\tilde{V}^*)^T y_\theta(t, \bar{\theta}) - 2\tilde{Q}(t, \tilde{V}^*)z_\theta(t, \bar{\theta}) \quad (62g)$$

$$y_\theta(t_f, \bar{\theta}) = 0. \quad (62h)$$

where, the H -minimal control $\tilde{V}^* = \tilde{V}^*(t, z(t, \bar{\theta}), z_\theta(t, \bar{\theta}), y(t, \bar{\theta}), y_\theta(t, \bar{\theta}))$ results from solving problem (60).

An optimal matrix $V^* = V^*(t)$ of regulator parameters is then given by

$$V^*(t) = \tilde{V}^*(t, z^*(t, \bar{\theta}), z_\theta^*(t, \bar{\theta}), y^*(t, \bar{\theta}), y_\theta^*(t, \bar{\theta})), \quad (63)$$

where $(z^*(t, \bar{\theta}), z_\theta^*(t, \bar{\theta}), y^*(t, \bar{\theta}), y_\theta^*(t, \bar{\theta}))$ is a solution of system (62a)–(62h).

Manutec r3

The method for finding optimal controls being insensitive with respect to random parameter variations presented here is applied now to the stochastic optimal feedback control of a manipulator (Manutec r3) with three rotational links (three degrees of freedom) [26].

Since for $\theta = \bar{\theta}$ or $\Delta p_D = \overline{\Delta p_D} = 0$, hence, if the vector of dynamic parameters is known, we also have

$$\Delta z(t, 0) = 0, y(t, 0) = 0, \quad (64a)$$

the Taylor expansion of $\Delta z(t, \omega), y(t, \omega)$ is reduced, cf. Equations (42a) and (42b); (56a)–(56c); and (62a)–(62h), to

$$\Delta z(t, \omega) \approx \Delta z_{\Delta p_D}(t, 0) \Delta p_D(\omega), \quad (64b)$$

$$y(t, \omega) \approx y_{\Delta p_D}(t, 0) \Delta p_D(\omega). \quad (64c)$$

Assuming that the payload mass $p_D(\omega)$ is a scalar stochastic variable, the expected Hamiltonian EH is given by, cf. Equation (61a),

$$\begin{aligned} EH(t, \Delta p_D, \Delta z, y, V) \\ = \sigma_{p_D}^2 \left(\Delta z_{\Delta p_D}(t, 0)^T \tilde{Q}(t, V(t)) \Delta z_{\Delta p_D}(t, 0) \right. \\ \left. + y_{\Delta p_D}(t, 0)^T A(V(t)) \Delta z_{\Delta p_D}(t, 0) \right. \\ \left. + y_{\Delta p_D}(t, 0)^T \begin{pmatrix} 0 \\ -M(t)^{-1} Y(t) \end{pmatrix} \right), \quad (65) \end{aligned}$$

where $\sigma_{p_D}^2$ denotes the variance of the scalar payload. As mentioned above, the minimization of Equation (65) subject to the

constraint

$$V \in D_t \quad (66)$$

can be done analytically in certain cases. Assuming, in the present example, that there are no constraints for the regulator parameters contained in V , the minimization of the expected Hamiltonian EH is carried out numerically for given function values $(\Delta z_{\Delta p_D}(t, 0), y_{\Delta p_D}(t, 0))$ at each time t .

With zero terminal costs, hence $G = 0$, because of Equations (64a)–(64c), in the present case, the two-point boundary value problem (62a)–(62h) is then reduced to

$$\begin{aligned} \Delta \dot{z}_{\Delta p_D}(t, 0) &= A(\tilde{V}^*) \Delta z_{\Delta p_D}(t, 0) + a_{\Delta p_D}(t, 0), \\ t_0 &\leq t \leq t_f, \end{aligned} \quad (67a)$$

$$\begin{aligned} \dot{y}_{\Delta p_D}(t, 0) &= -A(\tilde{V}^*)^T y_{\Delta p_D}(t, 0) - 2\tilde{Q}(t, \tilde{V}^*) \\ &\times \Delta z_{\Delta p_D}(t, 0), \quad t_0 \leq t \leq t_f, \end{aligned} \quad (67b)$$

$$\Delta z_{\Delta p_D}(t_0, 0) = 0 \quad (67c)$$

$$y_{\Delta p_D}(t_f, 0) = 0, \quad (67d)$$

where $\tilde{V}^*$ is obtained from the numerical minimization of the approximate expected Hamiltonian $EH(t, \Delta p_D, \Delta z, y, V)$, cf. Equation (65).

For the above described two-point boundary value problem we have then the following 12 state variables x_i , $i = 1, \dots, 12$:

$$\begin{aligned} x_1(t) &= \frac{\partial \Delta q_1}{\partial \Delta p_D}(t, 0), & x_7(t) &= \frac{\partial y_1}{\partial \Delta p_D}(t, 0) \\ x_2(t) &= \frac{\partial \Delta q_2}{\partial \Delta p_D}(t, 0), & x_8(t) &= \frac{\partial y_2}{\partial \Delta p_D}(t, 0) \\ x_3(t) &= \frac{\partial \Delta q_3}{\partial \Delta p_D}(t, 0), & x_9(t) &= \frac{\partial y_3}{\partial \Delta p_D}(t, 0) \\ x_4(t) &= \frac{\partial \dot{\Delta q}_1}{\partial \Delta p_D}(t, 0), & x_{10}(t) &= \frac{\partial y_4}{\partial \Delta p_D}(t, 0) \\ x_5(t) &= \frac{\partial \dot{\Delta q}_2}{\partial \Delta p_D}(t, 0), & x_{11}(t) &= \frac{\partial y_5}{\partial \Delta p_D}(t, 0) \\ x_6(t) &= \frac{\partial \dot{\Delta q}_3}{\partial \Delta p_D}(t, 0), & x_{12}(t) &= \frac{\partial y_6}{\partial \Delta p_D}(t, 0). \end{aligned}$$

Moreover, at the starting time point $t_0 = 0$ we have the initial conditions

$$x_1(0) = x_2(0) = \dots = x_6(0) = 0,$$

and the terminal conditions read:

$$x_7(t_f) = x_8(t_f) = \dots = x_{12}(t_f) = 0.$$

For simplification, we suppose now that the matrix $V(t)$ of regulator parameter functions has *diagonal* submatrices $K_p(t), K_d(t)$, cf. Equation (58a). Hence, the functions to be optimally determined are

$$\begin{aligned} v_1(t) &:= [K_p]_{11}(t) & v_2(t) &:= [K_p]_{22}(t) \\ v_3(t) &:= [K_p]_{33}(t) \end{aligned} \quad (68)$$

$$\begin{aligned} v_4(t) &:= [K_d]_{11}(t) & v_5(t) &:= [K_d]_{22}(t) \\ v_6(t) &:= [K_d]_{33}(t). \end{aligned} \quad (69)$$

In addition, we define

$$c_{ij} = [\tilde{Q}(t, V(t))]_{ij}. \quad (70)$$

Note that the needed representation of $\tilde{V}$ as a function of $t, \Delta z, y$ is obtained by minimizing the approximate expected Hamiltonian (65) with respect to the above mentioned elements $v_i = v_i(t)$, $i = 1, \dots, 6$.

Differential equation (67a) can then be represented by

$$\begin{aligned} \begin{pmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \\ \dot{x}_5 \\ \dot{x}_6 \end{pmatrix} &= \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ -v_1 & 0 & 0 & -v_4 & 0 & 0 \\ 0 & -v_2 & 0 & 0 & -v_5 & 0 \\ 0 & 0 & -v_3 & 0 & 0 & -v_6 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} \\ &+ \begin{pmatrix} 0 \\ 0 \\ 0 \\ -[(M(t))^{-1} Y(t)]_1 \\ -[(M(t))^{-1} Y(t)]_2 \\ -[(M(t))^{-1} Y(t)]_3 \end{pmatrix}, \end{aligned} \quad (71)$$

and Equation (67b) reads:

$$\begin{aligned} \begin{pmatrix} \dot{x}_7 \\ \dot{x}_8 \\ \dot{x}_9 \\ \dot{x}_{10} \\ \dot{x}_{11} \\ \dot{x}_{12} \end{pmatrix} &= \begin{pmatrix} 0 & 0 & 0 & v_1 & 0 & 0 \\ 0 & 0 & 0 & 0 & v_2 & 0 \\ 0 & 0 & 0 & 0 & 0 & v_3 \\ -1 & 0 & 0 & v_4 & 0 & 0 \\ 0 & -1 & 0 & 0 & v_5 & 0 \\ 0 & 0 & -1 & 0 & 0 & v_6 \end{pmatrix} \begin{pmatrix} x_7 \\ x_8 \\ x_9 \\ x_{10} \\ x_{11} \\ x_{12} \end{pmatrix} \\ &- 2 \begin{pmatrix} c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\ c_{21} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\ c_{31} & c_{32} & c_{33} & c_{34} & c_{35} & c_{36} \\ c_{41} & c_{42} & c_{43} & c_{44} & c_{45} & c_{46} \\ c_{51} & c_{52} & c_{53} & c_{54} & c_{55} & c_{56} \\ c_{61} & c_{62} & c_{63} & c_{64} & c_{65} & c_{66} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix}. \end{aligned} \quad (72)$$

Having representations (71) and (72), the two-point boundary value problems (67a)–(67c) is solved numerically by means of the multiple-shooting method BVPSOL (Boundary Value Problem Solver) [27]. According to Equation (53), the optimal feedback function $\varphi^* = \varphi^*(t, \Delta_q(t), \Delta_d(t))$ for the robot is then obtained, cf. Equations (54c) and (54d), from

$$D_{\Delta q} \varphi(t, 0, 0) = K(t) - M(t)K_p^*(t) \quad (73a)$$

$$D_{\Delta d} \varphi(t, 0, 0) = D(t) - M(t)K_d^*(t), \quad (73b)$$

where $V^*(t) = (K_p^*(t), K_d^*(t))$ results from the insertion of the solution of system (67a)–(67d) into the approximate H -minimal control $\tilde{V}^*$ obtained from minimizing the expected Hamiltonian (65) subject to $V(t)$.

In order to evaluate the tracking properties of the robust optimal feedback control law obtained by the above described method, we apply the obtained stochastic optimal regulator to 11 actual trajectories of the manipulator generated by 11 realizations of the random payload mass assumed to be $N(0,5)$ -normal distributed. We assume that these realizations lie in the confidence interval related to the confidence number α . Events having a probability smaller than $\frac{1-\alpha}{2}$, larger than $\frac{1+\alpha}{2}$, respectively are not taken into account. For $\alpha = 0.9$, the remaining range is then partitioned by equidistant points. The resulting realizations are given in the following table.

	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6
Probability of x	0.05	0.14	0.23	0.32	0.41	0.5
$p_D = \Phi^{-1}(x)$	1.7755	4.5985	6.3055	7.6615	8.8625	10
	Case 7	Case 8	Case 9	Case 10	Case 11	
Probability of x	0.59	0.68	0.77	0.86	0.95	
$p_D = \Phi^{-1}(x)$	11.1375	12.3385	13.6945	15.4015	18.2245	

The optimal feed forward control and the reference trajectory for a point-to-point trajectory optimization problem from the initial point

$$\begin{pmatrix} 0, 0 \\ 1, 5 \\ 0, 5 \end{pmatrix} \text{ to the terminal point } \begin{pmatrix} -2, 8 \\ 0, 2 \\ 0, 6 \end{pmatrix}$$

were computed by means of the stochastic robot optimization software (*OSTP*) [28]. The trajectories were computed by *SIMPACK* [29], a multibody simulation software package.

In the following Figs 3–8 the simulation results for the first link are presented. Here, $q_1 = q_1(t)$ denotes the rotational angle in the first link of the *Manutec r3*, and $u_1 = u_1(t)$ is the total input into the motor driving the first link.

In comparison with the behavior of standard PD controllers, the stochastic optimal feedback controller shows a much better performance in tracking the given reference trajectory in configuration space of the manipulator [25].

Figure 3. $q_1(t)$, $t_0 \leq t \leq t_f^{(0)}$.

Figure 4. $\Delta q_1(t)$, $t_0 \leq t \leq t_f^{(0)}$.

Figure 5. $\dot{q}_1(t)$, $t_0 \leq t \leq t_f^{(0)}$.

CONCLUSION

Approximation and numerical solution procedures have been presented for continuous-time optimal control problems with a convex cost criterion, a nonlinear random process differential equation, a random initial state, and deterministic or stochastic controls. Using

a parametric approach, the solution of the underlying dynamic equation represented by a system of first-order differential equations with random parameters has been considered first. Since closed-loop (CL) (feedback) controls can be approximated in practice very efficiently by means of open-loop feedback (OLF) controls, for practical applications it

Figure 6. $\Delta \dot{q}_1(t)$, $t_0 \leq t \leq t_f^{(0)}$.

Figure 7. $u_1(t)$, $t_0 \leq t \leq t_f^{(0)}$.

is sufficient to have efficient tools for finding optimal open-loop (OL) controls on arbitrary time intervals being most insensitive with respect to random parameter variations. Thus, random parameter variations have been incorporated into the optimal control design by using stochastic optimization methods for the minimization of the (conditional) expected total costs arising along the trajectory and at the terminal point.

For finding the stochastic optimal OL controls, first convex approximations of the resulting control problem under stochastic uncertainty are obtained by an “inner” linearization of the control problem, that is, by a linearization of the basic dynamic equation. Using then the necessary and sufficient optimality conditions for the convex approximation of the original problem, stochastic optimal control laws, so-called H -minimal

Figure 8. $\varphi_1(t, \Delta q(t), \Delta \dot{q}(t))$, $t_0 \leq t \leq t_f^{(0)}$.

controls, may be determined by solving a finite-dimensional stochastic optimization problem for the minimization of the expected Hamiltonian of the control problem subject to the remaining deterministic control constraints. Having the H -minimal controls, based on a Hamilton–Jacobi approach, stochastic optimal OL controls, may be then obtained by solving the related canonical or Hamiltonian system of first-order differential equations, which is a two-point boundary value problem with random parameters. Finally, having stochastic optimal OL controls for each remaining time interval, a stochastic optimal OLF control law follows.

Successful operation of the present method was shown for the optimal regulator design of robots under stochastic uncertainty.

CONTINUOUS-TIME MARTINGALES

DENIS SAURE

University of Pittsburgh, Department
of Industrial Engineering,
Pittsburgh, Pennsylvania

Modern martingale theory, introduced in large part by Doob [1], is a central component of the general theory of stochastic processes. Continuous-time martingales, the continuous-time analog of discrete-time martingales, are a fundamental tool in areas such as queueing, reliability, and stochastic calculus [2], to name but a few.

The classical example of a continuous-time martingale is the standard Brownian motion (a continuous-time version of a symmetric random walk; see **Brownian Motion**).

In fact, one of the main results in martingale theory, the Martingale representation theorem, asserts that many continuous-time martingales can be written as stochastic integrals with respect to the standard Brownian motion. In the sequel, we first define the concept of continuous-time martingale, followed by classical examples of such processes. Finally, we briefly present some of the main results in continuous-time martingale theory.

Definition. Consider a stochastic process $\{X(t) : t \geq 0\}$ defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$.

A collection $\{\mathcal{F}_t : t \geq 0\}$ of sub- σ -fields of $\mathcal{F}$ with the property that $\mathcal{F}_s \subset \mathcal{F}_t$ for all $s \leq t$ is called a *filtration*.

Here, $\mathcal{F}_t$ represents all of the information available at time $t \geq 0$. We say $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to the filtration $\{\mathcal{F}_t : t \geq 0\}$, if it satisfies the following three conditions:

- (i) $X(t)$ is $\mathcal{F}_t$ -measurable, for all $t \geq 0$,
- (ii) $\mathbb{E}[|X(t)|] < \infty$, for all $t \geq 0$, and
- (iii) $\mathbb{E}[X(t)|\mathcal{F}_s] = X(s)$, for all $0 \leq s \leq t$.

While conditions (i) and (ii) simply impose some regularity, condition (iii) essentially states that the best “prediction” about the state of the process at time t considering the information available at time $s \leq t$ is precisely its state at time s , that is, $X(s)$.

In many situations of interest, the filtration to be considered is that generated by the process itself, that is, $\mathcal{F}_t^X := \sigma\{X(s) : s \leq t\}$ (or by its *augmented* counterpart).

Remark. Note that, in general, martingales do not need to be indexed by $t \in \mathbb{R}_+$ and the definition applies to the case where $t \in T$ for some ordered set T .

In particular, by setting $T = \mathbb{N}$, we recover the definition of discrete-time martingales.

EXAMPLES

Example 1: Compensated Poisson Process. Let $\{N(t) : t \geq 0\}$ denote a Poisson process with a homogeneous rate $\lambda > 0$ equipped with the filtration generated by itself (i.e., $\{\mathcal{F}_t^N : t \geq 0\}$). Define $X(t) := N(t) - \lambda t$, for all $t \geq 0$. Note that $X(t)$ is $\mathcal{F}_t^N$ -measurable, that $\mathbb{E}[|X(t)|] \leq 2\lambda t$, for all $t \geq 0$, and that

$$\begin{aligned} \mathbb{E}[X(t)|\mathcal{F}_s^N] &= \mathbb{E}[N(t) - N(s) + N(s) - \lambda t|\mathcal{F}_s^N] \\ &= \mathbb{E}[N(t) - N(s)|\mathcal{F}_s^N] + \mathbb{E}[N(s) - \lambda t|\mathcal{F}_s^N] \\ &= \lambda(t - s) + N(s) - \lambda s = X(s), \end{aligned}$$

for all $0 \leq s \leq t$, where we have used the independent- and stationary-increments properties of the Poisson process. We conclude that the process $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to $\{\mathcal{F}_t^N : t \geq 0\}$.

Example 2: Standard Brownian Motion. The standard Brownian motion is the classical example of a continuous-time martingale. Consider the *standard Brownian filtration* $\mathcal{F}_t^B := \sigma\{B(s) : s \leq t\}$, where

$\{B(t) : t \geq 0\}$ denotes a standard Brownian motion.

The fact that $B(t)$ is $\mathcal{F}_t^B$ -measurable is evident; by Jensen's inequality we have $\mathbb{E}[|B(t)|]^2 \leq \mathbb{E}[B(t)^2] = t < \infty$ for all t , and, if $s < t$, then

$$\begin{aligned}\mathbb{E}[B(t)|\mathcal{F}_s^B] &= \mathbb{E}[B(t) - B(s)|\mathcal{F}_s^B] + \mathbb{E}[B(s)|\mathcal{F}_s^B] \\ &= 0 + B(s),\end{aligned}$$

where we have used the independent- and stationary-increments properties of the standard Brownian motion, and the fact that $B(s)$ is $\mathcal{F}_s^B$ -measurable. Thus, we have that the standard Brownian motion is a continuous-time martingale with respect to the standard Brownian filtration.

Example 3: A Second Brownian Martingale. Consider the process $\{X(t) : t \geq 0\}$, with $X(t) := B(t)^2 - t$ for all $t \geq 0$, where $\{B(t) : t \geq 0\}$ denotes a standard Brownian motion, and consider the standard Brownian filtration. $X(t)$ is trivially $\mathcal{F}_t^B$ -measurable; we can check that $\mathbb{E}[|X(t)|] \leq \mathbb{E}[B(t)^2] + t = 2t < \infty$ for all $t \geq 0$, and that

$$\begin{aligned}\mathbb{E}[X(t)|\mathcal{F}_s^B] &= \mathbb{E}[(B(t) - B(s))^2 - t|\mathcal{F}_s^B] \\ &= \mathbb{E}[(B(t) - B(s))^2|\mathcal{F}_s^B] + 2\mathbb{E}[(B(t) - B(s))B(s)|\mathcal{F}_s^B] + \mathbb{E}[B(s)^2 - t|\mathcal{F}_s^B] \\ &= t - s + 0 + B(s)^2 - t = X(s),\end{aligned}$$

for all $0 \leq s \leq t$.

We conclude that $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to the standard Brownian filtration.

Example 4: Exponential Martingale for Brownian Motion. The following process, known as the *exponential martingale for Brownian motion*, has played a key role in modeling the evolution of asset prices in finance. For $\theta > 0$, set $X(t) := \exp(\theta B(t) - \theta^2 t/2)$ for all $t \geq 0$, where $\{B(t) : t \geq 0\}$ represents a standard Brownian motion.

Note that $\mathbb{E}[|X(t)|] = \mathbb{E}[\exp(\theta^2 t/2 - \theta^2 t/2)] = 1$, for all $t \geq 0$, and that

$$\begin{aligned}\mathbb{E}[X(t)|\mathcal{F}_s^B] &= X(s)\mathbb{E}[\exp(\theta(B(t) - B(s)) - \theta^2(t-s)/2)|\mathcal{F}_s^B] \\ &= X(s),\end{aligned}$$

where we have used the independent- and stationary-increments properties of the standard Brownian motion.

We conclude that $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to the standard Brownian filtration.

Example 5: Doob's Martingale. Let Y be a real-valued random variable on $(\Omega, \mathcal{F}, \mathbb{P})$ such that $\mathbb{E}[|Y|] < \infty$.

For a given filtration $\{\mathcal{F}_t : t \geq 0\}$, define $X(t) := \mathbb{E}[Y|\mathcal{F}_t]$ for $t \geq 0$. We can show that $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to $\{\mathcal{F}_t : t \geq 0\}$.

Indeed, we have that $X(t)$ is trivially $\mathcal{F}_t$ -measurable, that

$$\mathbb{E}[|X(t)|] = \mathbb{E}[\mathbb{E}[|Y|]|\mathcal{F}_t] = \mathbb{E}[|Y|] < \infty,$$

and that, for $s \leq t$,

$$\mathbb{E}[X(t)|\mathcal{F}_s] = \mathbb{E}[\mathbb{E}[Y|\mathcal{F}_t]|\mathcal{F}_s] = \mathbb{E}[Y|\mathcal{F}_s] = X(s),$$

by the tower property of conditional expectation and the fact that $\mathcal{F}_s \subset \mathcal{F}_t$.

SOME IMPORTANT RESULTS

Here, we present some of main results for continuous-time martingales. The optional stopping theorem and the Martingale convergence theorem are covered in a separate article (see **Theory of Martingales**).

Doob's Maximal Inequality

The following result (e.g., Ref. 3, Theorem 4.2) bounds the probability that a martingale exceeds certain threshold on a given time interval.

Suppose $\{X(t) : t \geq 0\}$ is a continuous-time martingale with respect to some filtration, and that $X(t) \geq 0$ almost surely (a.s.) for all $t \geq 0$. Then, for any $\lambda > 0$ and $p > 1$ we have that

$$\lambda^p \mathbb{P} \left\{ \sup_{\{s: 0 \leq s \leq t\}} X(s) > \lambda \right\} \leq \mathbb{E}[X(t)^p].$$

The previous result is also valid in the case where $\{X(t) : t \geq 0\}$ is a non-negative sub-martingale (see **Theory of Martingales**).

Martingale Representation Theorem

The martingale representation theorem (e.g., Ref. 3, Theorem 12.3) is one of the main results in Martingale theory.

Roughly speaking, the theorem asserts that, under some regularity conditions, *any* continuous-time martingale $\{X(t) : t \geq 0\}$ with respect to the standard Brownian filtration can be written as a stochastic (Itô) integral, and that such a representation is unique.

In particular, we have that

$$X(\omega, t) = \int_0^t f(\omega, s) dB(\omega, s) \quad \text{for all} \\ 0 \leq t \leq T, \omega \in \Omega, \quad (1)$$

for a unique $\mathcal{F}^B$ -adapted process f (i.e., $f(t)$ is $\mathcal{F}_t^B$ -measurable for all $0 \leq t \leq T$) such that

$$\int_0^T f(t)^2 dt < \infty \quad a.s.$$

provided that $\mathbb{E}[X(T)^2] < \infty$.

Moreover, the theorem asserts that any such process $\{f(t) : t \geq 0\}$ defines a continuous-time martingale for $t \in [0, T]$ via (1). This result is central to the theory of stochastic integration. In finance, the martingale representation theorem is fundamental in establishing the existence of hedging strategies.

Girsanov Theorem

Let $\{f(t) : 0 \leq t \leq T\}$ be an $\mathcal{F}^B$ -adapted process such that $\int_0^T f(t) dB(t) < \infty$ a.s., and define

$$X(t) := \exp \left\{ -\frac{1}{2} \int_0^t f(s)^2 ds + \int_0^t f(s) dB(s) \right\} \\ 0 \leq t \leq T.$$

If $\mathbb{E}[X(T)] = 1$, then $\{X(t) : 0 \leq t \leq T\}$ is a continuous-time martingale with respect to $\{\mathcal{F}_t^B : t \geq 0\}$, and the process defined by

$$B'(t) := B(t) - \int_0^t f(s) ds \quad 0 \leq t \leq T$$

is a standard Brownian motion with respect to $\{\mathcal{F}_t^B : t \geq 0\}$ in the probability space $(\Omega, \mathcal{F}_T^B, Q)$, where Q is defined

as $Q(A) := \mathbb{E}[\mathbf{1}\{A\}X(T)]$, $A \in \mathcal{F}_T^B$, and $\mathbf{1}\{\cdot\}$ denotes the indicator function.

The first part of the result generalizes Example 4. The second part of the result is of critical importance in finance, as it facilitates pricing financial instruments under alternative measures, where the value of underlying assets are continuous-time martingales.

Additional Convergence Results

A special class of martingales are the uniformly integrable [4] martingales, which can guarantee to converge with probability one to a terminal integrable random variable X_∞ ; moreover, convergence is also extended to first moments. For square integrable martingales, a subset of the former, convergence is also extended to second moments, and Doob's maximal inequality can be extended (see, e.g., Ref. 2) to show that

$$\mathbb{E} \left[\sup_{\{s: 0 \leq s \leq t\}} X(s)^2 \right] \leq 4 \sup_{\{s: 0 \leq s \leq t\}} \mathbb{E}[X(s)^2] \leq 4 \mathbb{E}[X_\infty^2].$$

APPLICATIONS AND FURTHER READING

Applications

Continuous-time martingales are used to analyze phenomena in many application areas. In finance, martingale theory is used in pricing of finance derivatives; see Chapter 14 in Ref. 3 for a review of applications in this area. In queueing, martingales are used to support asymptotic approximations to queueing models; see Ref. 5 for a review of the application of martingales in this subject.

Martingales have also been applied to statistical inference (e.g., filtering problems [6], Chapter 1), which arise naturally in many areas of interest.

In Operations Research and Management Science (excluding applications to finance), martingales have been applied to analyze problems in conflict resolution [7], revenue management [8,9], supply chain management [10], forecasting [11,12], queueing [13], to name but a few.

Further Reading

Rigorous treatment of continuous-time martingales is technically complex. This article provides only a brief introduction to some of the main results: an accessible (but still rigorous) treatment of the subject can be found in Refs [14] and [15]. See also Refs [16] and [17] for an introduction to martingale concepts. We refer the reader to Ref. 2 for a detailed and rigorous treatment of the subject. References [18] and [19] cover continuous-time martingales from a pure stochastic-process perspective, and Ref. 3 does the same while presenting the fundamentals of stochastic calculus, together with a comprehensive review of its applications to finance. Reference [20] provides an alternative treatment, oriented toward the study of point process dynamics.

CONTRIBUTIONS TO SOFTWARE RELIABILITY WITH OR APPLICATIONS

P.K. KAPUR
RAVI KUMAR
ANSHU GUPTA
Department of Operational
Research, University of Delhi,
Delhi, India

Computer software is the single most important technology in the human world, and an excellent example of the *law of unintended consequences*, as it paves the way for the creation of the new (e.g., genetic engineering), extension of the existing (e.g., telecommunications), and demise of the older (e.g., the printing industry) technologies. Software plays a dual role. In the first role, it is a product that delivers computing potential embodied by computer hardware (e.g., mathematical software), while in the second role it is a vehicle for delivering a product (e.g., software inside the cellular phones). Today almost all businesses, industries, services, government agencies, and even our day-to-day activities are directly or indirectly affected by computing systems. For example, air traffic control, nuclear reactors, patient monitoring system in hospitals, mechanical and safety control in automobiles, on-line ticketing, industrial process control, global networking, information storing, sharing, and so on, are some of the diverse applications. Improvements in hardware performance, reflective changes in computing architectures, gigantic increase in storage capacity, and a huge variety of exotic input and output options have further increased the demand for software in the automation of complex systems and its use as a solving tool for many complex problems. Size and design complexities of the software have also increased many folds and the trend will certainly continue in future. For instance, the National Aeronautics and Space Administration's (NASA) space

shuttle flies with approximately 0.5 million lines of software code on board and 3.5 million lines of code in ground control and processing [1–3].

The computer revolution has benefited society and increased the global productivity many folds, but a major threat of this revolution is that the world has become critically dependent on them for the proper functioning and timing of all its activities. The penalty of a failure may range from inconvenience in social life to economic damage to loss of life. A total breakdown of the system functioning is observed in many cases until the fault is repaired, and even after restoration to the normal state, sometime it takes up huge time, effort, and resources to make up the losses. There are several instances when software failures have caused severe loss to the economy and to human lives. A few examples are the crash of a Boeing 727 of Mexicana airlines (1986), the overdose given to cancer patients by a massive Therac-25 radiation machine in Marietta (1985 and 1986), blackouts in the northeastern United States during the month of August, 2003, and so on [3]. The ability to design, test, and maintain software has grown reasonably but many further improvements are, however, still desired. The software development process (SDP) is a challenging task for the developers. Certainly, the most important SDP problem even now is building it to customer demands so that it is *more reliable*, *built faster*, and *built cheaper* (in general order of importance). Success in meeting these demands affects the market share and profitability of the developers. These conflicting demands have resulted in risk and intense pressure, and therefore created a strong need for a practice that can help to have a tight control over the SDP and develop software to the needs of the software market.

In the early 1970s, the software reliability engineering (SRE) discipline emerged to establish and use sound engineering principles in order to economically obtain software that were not only reliable but also worked

efficiently on real machines, bringing the SDP under the engineering umbrella. The immediate concern of SRE was aimed at scheduling and systematizing the SDP to control the various stages using its tools, methods, and processes to engineer quality software. SRE broadly focuses on quantitatively characterizing the standardized six quality characteristics defined by the International Organization for Standard/International Electrotechnical Commission (ISO/IEC): functionality, usability, reliability, efficiency, maintainability, and portability. *Software Reliability* (SR) is considered the key quality characteristic—a *must-be quality*—as it quantifies software failures—the most unwanted events, making SR a major concern to the developers and users alike. Unlike hardware, any software developed anew is put on test throughout the SDP to satisfy software quality even though it is built on the most recent and productive SRE tools and techniques. The achieved quality level by means of testing has no meaning unless it is measured quantitatively to build confidence in its level. Besides this, many decisions such as release time, resource allocation in testing, as well as those related to the post release (post delivery maintenance cost and warranty) can be made more accurately only if a quantitative measure of quality is known. All this needs measurement technologies to assess the software quality. Software reliability growth models (SRGMs) based on stochastic and statistical principles are the most important and most successful tools to assess software reliability quantitatively.

Studies in SR modeling started as early as in the 1960s. The issues-related reliability measurement arose even at the time of birth of computing systems, but because of high cost and low software and hardware productivity, the concepts of SR were at the infancy stage. Most of studies were concerned with productivity and quality of hardware systems. Haugk *et al.* [4] presented some experimental results concerning the testing of a switching system in which software was an essential part, but there was no direct approach. The first paper on SR modeling appears to have been published in 1967 by Hudson [5]. He viewed software

development as a birth-and-death process in which fault generation corresponded to birth and fault correction to death and obtained a Weibull distribution of intervals between failures. Jelinski and Moranda's work [6] is recognized as the second major step. They assumed a hazard rate for failures that was piecewise constant and proportional to the remaining fault number. The hazard rate changed at each fault correction by a constant amount, but was constant between corrections. They further proposed two variants known as the *JM Geometric model* and the *Moranda Geometric Poisson model* [7]. The 1970s was the most significant in the SR study, as some of the models [6–13] proposed in this decade later formed the basis for further research in the field and found many practical applications.

Shooman [8] viewed the hazard rate as being determined by the rate at which execution of the program results in the remaining faults being passed and the remaining faults are assumed to depend on the number of faults corrected. The correction rate was assumed to be related to the project personnel profile in time proposing several fault correction profiles: the choice depending on the particular project. Schneidewind [9,10] investigated different reliability functions—exponential, normal, gamma, and Weibull—for estimating SR and suggested the choice of the best. He also suggested that the time lag between failure detection (FD) and fault correction (FC) be determined from actual data and used to correct the timescale in forecasts. In early 1975, Musa [11] proposed an execution time model of SR. This model was later studied and applied on many real applications and yielded good results for many. Musa considered execution time in two respects: the operating time of a product delivered to the field and the cumulative execution time that had occurred during test phases of the SDP as well as during post delivery maintenance. The hazard rate was assumed to be constant with respect to operating time but a function of the faults remaining and hence the cumulative execution time. The fault removal rate (FRR) was proportional

to the fault detection rate (FDR), making consideration of debugging personnel profiles unnecessary. A calendar time component was also developed that related execution time to calendar time. Littlewood and Verrall [12] worked out an SRGM based on Bayesian approach. The authors modeled the hazard rate as a random process for the failures experienced.

Goel and Okumoto [13] proposed an SRGM (called the *GO model*) that describes the failure detection as a nonhomogeneous Poisson process (NHPP) assuming that the hazard rate is proportional to the remaining fault number. This paper was a pioneering attempt in SR modeling. Later researchers proposed many SRGMs that describe the FD and/or FC process by NHPP following the basic assumption of the GO model and the research is still continuing. Starting from the late 1960s and approximately in the past 40 years, a vast literature of SR models based on NHPP has been developed. These models have been widely studied and applied on real software projects. Considering the dynamic software testing and debugging (ST&D) process, many new concepts of SR modeling have been studied and incorporated. In this article, we will give an overview of many SRGMs and discuss a few unified approaches for developing the SRGM. In the later sections of the article, we will also give an overview of a few operations research (OR) applications of SR modeling.

Notation

$m(t)$:	expected number of failure/removal by time t , with $m(0) = 0$
$m_f(t), m_{if}(t)$:	expected number of software (or module i /type i) failure by time t ; $m_f(0) = 0$
$m_r(t), m_{ir}(t)$:	expected number of software (or module i /type i) fault removals by time t ; $m_r(0) = 0$
$m_i(t), m_{ii}(t)$:	expected number of software fault (or module i /type i) isolations by time t ; $m_{ii}(0) = 0$
$a(a_i)$:	initial error content in software (or module i /type i) before software testing

$b(t), b_i(t)$:	time dependent FDR/FRR per remaining faults
$b(b_i)$:	constant FDR/FRR per remaining faults in software (module i /type i) $0 < b < 1$
β, c :	constant parameter
$W(t), W_i$:	expected cumulative amount of test effort by time t with $w(t)$ as its density function
τ :	change point

SRGM: AN OVERVIEW AND UNIFIED MODELING APPROACH

A number of instances have demonstrated that execution time is superior to the calendar time [14]. However, since the quantities in terms of calendar time component are more meaningful to engineers and managers, most of the models were developed on the calendar time component. Most of the earlier models assumed that, whenever an attempt is made to remove a detected fault, it is removed perfectly and no new faults are generated (perfect debugging environment). The earliest model in this category was the GO model [13]. It is based on the following simple assumptions:

1. Failure Observation phenomenon is modeled by NHPP.
2. Failures are observed during execution caused by the remaining faults in the software.
3. An immediate effort is made to find the cause of detected failures and the isolated faults are removed prior to future test occasions.
4. All faults in the software are mutually independent.
5. The debugging process is perfect and no new fault is introduced during debugging.

The above assumptions can be described mathematically with the following differential equation:

$$d/dt(m(t)) = b(a - m(t)), \quad (1)$$

which under the initial condition

$$m(0) = 0 \quad \text{yields} \quad m(t) = a(1 - e(-bt)). \quad (2)$$

The model is known as the exponential NHPP model, as it describes an exponential failure curve, and has been applied to a variety of testing environments in practice as it provides good estimation and prediction of reliability. Following the GO model, other exponential SRGMs have been proposed by Ohba [15] and Yamada and Osaki [16]. Ohba assumed that the software consists of a number of independent modules, whereas Yamada and Osaki assumed that there are two types of errors in the software. These models describe the failure phenomenon for each module/error type by the GO model with different parameters, and the mean value function (MVF) is the sum of the MVFs for each module/error type. The early models were exponential, accounting the uniform operational profiles, which may be unrealistic in many real testing profiles. For nonuniform profiles, many researchers later attempted to develop models describing S-shaped failure curves, attributing the S-shapedness to the distinctive explanations.

First, Yamada *et al.* [17] refined the GO model describing testing as a two-stage process, namely FD and FC, and assuming that fault removal follows failure detection with a time lag

$$\begin{aligned} d/dt(m_f(t)) &= b(a - m_f(t)) \quad \text{and} \\ d/dt(m_r(t)) &= b(m_f(t) - m_r(t)). \end{aligned} \quad (3)$$

Solution of the above is

$$\begin{aligned} m_f(t) &= a(1 - e(-bt)) \quad \text{and} \\ m_r(t) &= a(1 - (1 + bt)e(-bt)). \end{aligned} \quad (4)$$

S-shaped SRGMs [18–20] have similar mathematical forms but are developed under a different set of assumptions. An important characteristic of most S-shaped models is that these models can describe both exponential and S-shaped growth curves depending on the parameter values and therefore termed as flexible models. SRGM, which uses calendar time or execution time as the

unit of FD and/or FC period, either assumes a constant or does not explicitly consider the testing effort and its effectiveness. The reliability growth during testing is highly related to the amount of resources (test efforts) spent on detecting and correcting latent faults. A testing effort function describes the distribution of testing resources (CPU time, manpower, number of executed test cases, etc.) during the testing period. Many researchers [21–26] have proposed SRGMs describing the relationship among the testing time, testing effort, and the number of software faults detected. The time-dependent behavior of test-effort expenditures has been described by exponential, Rayleigh, Weibull, logistic, or generalized logistic functions in the literature. Following the GO model, the first NHPP-based SRGM with respect to test effort intensity $w(t)$ is as follows from Ref. 27:

$$d/dt(m(t))/w(t) = b(a - m(t)). \quad (5)$$

The MVF of the model is given as

$$m(t) = a(1 - e(-bW(t))). \quad (6)$$

In applications, first, the best testing effort function is fitted to the observed test effort data and then the parameters of the SRGM for the FD and/or FC process are determined with reference to the estimated test effort data. Later, the effect of testing efforts were studied on many other existing models.

One aspect of major importance to the SR modeling study is testing efficiency. In practice, testing efficiency is usually imperfect. During debugging, the debuggers can remove a fault perfectly; it may be repaired imperfectly, which causes failure again [called *imperfect fault removal* (IFR)], or the original fault is removed perfectly but a new one may be generated (called *fault generation* (FG)), producing some other kind of failure when checked on the same input on removal of the original fault. IFR causes more failures but the fault content remains the same; however, due to FG, the number of failures increases because of increased fault content. The concept of testing efficiency was first introduced by Goel and Okumoto [28] in the JM model.

Kapur and Garg [29] assumed that the FRR per remaining faults is reduced by imperfect debugging in the GO model, that is,

$$\begin{aligned} d/dt(m_r(t)) &= pb[a - m_r(t)] \quad \text{and} \\ d/dt(m_f(t)) &= b[a - pm_f(t)]. \end{aligned} \quad (7)$$

Solution of Equation (7) under the initial conditions $m_r(0) = 0$ and $m_f(0) = 0$ is

$$\begin{aligned} m_r(t) &= a(1 - e^{-bpt}) \quad \text{and} \\ m_f(t) &= (a/p)(1 - e^{-bpt}). \end{aligned} \quad (8)$$

If $p = 1$, the model reduces to the GO model with $m_r(t) = m_f(t)$.

Obha and Chou [30] proposed the first NHPP SRGM incorporating the effect of FG, defined as

$$\begin{aligned} d/dt(m(t)) &= b(t)[a(t) - m(t)] \quad \text{with} \\ b(t) &= b, a(t) = a + \alpha m(t). \end{aligned} \quad (9)$$

Hence the MVF of the SRGM is

$$m(t) = (a/1 - \alpha)(1 - e(b(1 - \alpha)t)). \quad (10)$$

Yamada *et al.* [31] proposed an exponential and a linear function for the FG ($a(t) = ae^{\alpha t}$ and $a(t) = a(1 + \alpha t)$), respectively. Pham *et al.* [32] incorporated the effect of learning on ST&D teams in imperfect debugging models. Zang *et al.* [33] integrated the two types, modeling it on the number of failures experienced. However, the FG rate is expected to be proportional to the FC rates, and hence later Kapur *et al.* [34] comprehensively integrated the two types of imperfect debugging, clearly illustrating the concept of imperfect debugging.

A few other interesting and important aspects of ST&D process studied and incorporated by the several researchers are complexity of faults, measuring reliability in operational phase, fault dependency and debugging (FD&D) time lag, distributed development environment (DDE) modeling, change point analysis, etc. Some researchers tried to study each aspect individually, while others have integrated distinct aspects into single model.

Faults may require different amounts of testing effort and strategy for removal. Yamada and Osaki [16] modified the GO model, defining faults in two categories and assuming different FDR/FRR. The MVF of their SRGM is

$$m(t) = \sum_{i=1}^2 m_i(t) = a \sum_{i=1}^2 p_i(1 - e^{-b_i t}). \quad (11)$$

Here, subscript i defines the fault type and it is expected that $0 < b_2 < b_1 < 1$. Kareer *et al.* [35] modified this model assuming a time-dependent FRR for both types of faults. The FC phenomenon of simple faults is described by an exponential SRGM, while an S-shaped SRGM is used for hard faults. Kapur *et al.* [36] introduced a generalized Erlang SRGM, classifying the faults as simple, hard, and complex. It is assumed that the time delay between the FD&FC represents the complexity of the faults. The more complex the fault, the more the time delay. The model has been extended to n types of faults. For simple faults, it is assumed that the removal follows immediately after detection and the GO model is used to describe their MVF. FD&FC is modeled as a two-stage process for hard faults, and delayed S-shaped SRGM [17] is used for their MVF. FD&FC for complex faults is modeled as a three-stage process (Erlang growth curve), namely, observation, isolation, and removal, and hence the model is formulated as

$$\begin{aligned} dm_{3f}(t)/dt &= b_3[a_3 - m_{3f}(t)] \\ dm_{3i}(t)/dt &= b_3[m_{3f}(t) - m_{3i}(t)] \\ dm_{3r}(t)/dt &= b_3[m_{3i}(t) - m_{3r}(t)] \\ m_3(t) &= m_{3r}(t) = a_3(1 - (1 + b_3 t \\ &\quad + (b_3^2 t^2 / 2))e^{-b_3 t}). \end{aligned} \quad (12)$$

Failure curves for hard and complex faults behave similar to the simple faults in the steady-state, and MVF of the SRGM describing the joint effect of the different types of faults is

$$m(t) = m_1(t) + m_2(t) + m_3(t), a_1 + a_2 + a_3 = a. \quad (13)$$

Such a modeling enables the management to effectively plan and control the testing strategy to tackle each type of fault. Some SRGMs also integrated the effect of learning of the ST&D teams, change point, and FD&D time lag in the Erlang Model [37,38].

The models discussed so far have been formulated under a common assumption that the FDR/FRR is a constant/continuous function of time over the entire testing period. In practice, it can change with time as the testing progresses. For example, consider that the testing of software is started initially by a testing team and after two days of testing the management changes the team constitution by including a new member possessing better technical skills in order to speed up the testing. This reconstitution can change the behavior of the testing process completely. Such changes are often seen in the software development. There are many factors that can change during the testing process. These include the testing environment, testing strategy, complexity and size of the functions, defect density, skill, motivation and constitution of the ST&D teams, and so on. The idea can be analyzed using the *change point concept*, and the time point where the change is observed is termed as the *change point*. The idea is that the testing period is divided into time intervals, and it is assumed that during a particular interval the testing strategy and environment are more or less similar but are slightly different from the other intervals. The FDR/FRR is either assumed to be constant or a function of testing time during each interval but varies from the other intervals. Zhao [39] started the concept of change point and introduced it in hardware reliability. Some important contributions in this area are given in Refs 38,40–43. Chang [41] introduced this concept into the GO model with a single change point defining FDR as

$$b(t) = \begin{cases} b_1 & 0 \leq t \leq \tau; \\ b_2 & t > \tau \end{cases}. \quad (14)$$

The position of the change point can be judged from the actual failure data curve, using some software package such as change point analyzer, or it can be treated as an

unknown model parameter. The MVF for the SRGM is given as

$$m(t) = \begin{cases} [a(1 - e^{-b_1 t})] & 0 \leq t \leq \tau; \\ [a(1 - e^{-b_1 \tau - b_2(t-\tau)})] & t > \tau. \end{cases} \quad (15)$$

Shyur [42] defined the GO model with change point under imperfect debugging environment. The model is extended to analyze the fault complexity. Further, Huang [40] reanalyzed the Chen model with respect to generalized logistic testing effort function. Kapur *et al.* [43] studied the change point concept in the Kapur and Garg [20] model with respect to time and testing efforts. Kapur *et al.* [38] have also integrated change point and fault complexity with DDE. They have also carried out testing effort control problems on some of these models.

To handle the complexities of SDP, developers tend to develop and maintain the software under DDE. Here, the SDP is realized by mapping the full set of system requirements across the various subsystems, which are later integrated to make the complete software. Development of each subsystem is distributed to various teams who develop their modules independently. Some of the modules are build on the existing software/modules which are modified and extended to engineer the new release, while some of them are wholly new components. The role of SRGM is still important in controlling and managing the development of quality software. The first attempt in SR modeling under DDE was due to Yamada *et al.*, [44] who assumed that the software consists of n used and m newly developed components. Failure phenomenon for the used component was described by GO model, while the new components used the S-shaped [17] model. The MVF for the software system is the sum of the MVFs of its entire components, that is,

$$m(t) = a \left[\sum_{i=1}^n p_i (1 - e^{-b_i t}) + \sum_{j=1}^m p_{n+j} \times \left\{ 1 - \{1 + b_{n+j} t\} e^{-b_{n+j} t} \right\} \right]. \quad (16)$$

Kapur *et al.* [45] extended the analysis of DDE and formulated flexible testing coverage and test-effort-based SRGM for DDE.

A conventional assumption of many SRGMs is that the detected faults are immediately removed. ST&D is a time-consuming and expensive process. The time to remove faults depends on their complexity, skills of the ST&D team, the software development environment, and so on. In the general, fault removal may take a longer time after detection, with more removals in the later phases of testing. Therefore, the time delay in the FC process after the FD process cannot be ignored. Besides this, Ohba [18] and Kapur and Garg [20] visualized that software faults are of two types: mutually independent (removed on the detection of a failure) and mutually dependent (gets removed during the removal of some leading faults). Mutually dependent faults can be removed if the faults leading to them are removed. Schneidewind [10] first modeled the fault correction process using a constant delayed fault detection process. Later Xie and Xhao [46] extended this by assuming a time-dependent delay function. Delayed S-shaped model [17] and fault complexity models also consider the time lag between FD and FC. Kapur and Younes [47] analyzed the SR considering the FD&D time lag. Huang and Lin [48] described FD by the GO model, and assuming $\phi(t)$ to be the delay factor, the FC process was given by

$$m_r(t) = m_f(t - \phi(t)) = a(1 - e^{-b(t - \phi(t))}). \quad (17)$$

Various conventional models are derived using different forms of $\phi(t)$. For example, if $\phi(t) = 0$, we obtain the GO model; for $\phi(t) = (1/b)\ln(1 + bt)$ and $\phi(t) = (1/b)\ln((1 + \beta)e^{-bt}/1 + \beta e^{-bt})$ the SRGMs in Refs 17 and 18 respectively, are obtained. Singh [49] incorporated the learning phenomenon using a power function for FDR/FRR in Ref. 14. Xie *et al.* [50] and Wu *et al.* [51] proposed the SRGM claiming that fault-correction SRGM can be defined for the existing fault detection SRGM using different forms of delay functions. With

intensity $\lambda_f(t)$, $m_f(t)$ is given as

$$m_f(t) = \int_0^t \lambda_f(s) ds \quad (18)$$

and with a delay function $\Delta(t)$, MVF of the removal process is defined as

$$m_r(t) = \int_0^t \lambda_r(s) ds = \int_0^t E[\lambda_f(s - \Delta(s))] ds. \quad (19)$$

Assuming $\lambda_f(t)$ as in the GO model, various SRGMs were obtained assuming constant, time-dependent, and random correction times.

Besides modeling for the testing phase, a few researchers have extended their SRGMs to the operational phase to compute the remaining fault number at release time and field failure rate to track the system performance. It is stated that, however, close we claim the test environment is to the operational environment, it cannot be a mirror image. Along with this, removals in this phase can be non instantaneous or deferred because of several reasons. Kapur *et al.* [52] claimed that for SR analysis in operational phase, software must be categorized in two types: *project type* (special purpose) or *product type* (general-purpose). During the testing phase, the software type does not affect the reliability growth. However, the type of software also influences the reliability growth during the operational phase. Tracking the system performance is not difficult for the project-type software since it used on a few readily monitored systems under almost constant usage rate. However, it is difficult for the product-type software due to the wide distribution of the software where the usage typically builds to several thousand independent systems. Kenny [53] argued that the number of failures in the operational phase is strongly influenced by the number of users and proposed a model that includes a factor for the usage rate during the operational phase. Under the assumption that the average number of failures is a function of the number of encountered defects, which is a function of the number of instructions executed up to

the testing time t , the model is

$$\begin{aligned} dm/dt &= (dm/dx)(dx/de)(de/dt) \\ &= b_1^* b_2 r^* b_3 t^k. \end{aligned} \quad (20)$$

Equation (20) yields

$$\begin{aligned} m(t) &= a \left(1 - e \left(-b \left(t^{k+1}/(k+1) \right) \right) \right), \\ b &= b_1 b_2 b_3, \end{aligned} \quad (21)$$

where a is the number of faults at the time of release of the software and r is the remaining number of faults during the field use. This model uses a power function to describe the software usage, which grows as the number of software users increases, particularly for product-type software. In the marketing literature, power function is seldom used for describing the user growth over time. Kapur *et al.* [54] redefined the Kenny's model using the Bass [55] model of innovation diffusion to describe the user growth. They further modified their model under imperfect debugging environment and linking appropriate usage function to both types of software [52].

Apart from all the models discussed above, there are several other SR modeling interests that have gained popularity in recent years, although they have quite older origins such as stochastic differential equations based models, reliability estimation with neural networks, discrete SRGM, and so on. The existing research NHPP models are formulated considering diverse ST&D environments and have been applied successfully to various testing environments but not in the general case: that is, a particular SRGM cannot be applied in general, as the physical interpretation of the ST&D is not general. A solution to this problem is to develop unified modeling (UM) approaches. For any particular application, one needs to study several models and then decide the most appropriate ones. The selected models are then compared on the basis of the results obtained, and a model is selected. Alternatively, following a unification approach several SRGMs can be obtained from a single approach, giving an insightful investigation for these models without making many distinctive assumptions. It can make the task of model

selection and application much simpler. Establishment of a unification methodology is one of the recent topics of study in this area.

Some researchers have worked on formulating generalized approaches. Work in this area started with Shanthikumar [56], who proposed a generalized birth process model to describe both the JM and GO models. Langberg and Singpurwalla [57] showed that several SR models can be viewed from the Bayesian point of view. Miller [58] extended their idea such that the MVF in NHPP models can be characterized by the pdf of fault detection time. Haung *et al.* [59] discussed a unified scheme for discrete time NHPP models by applying the concept of means. In 2009, Kapur *et al.* [60,61] proposed two approaches—first based on infinite server queueing theory and second characterizing MVF from failure distribution considering testing efficiency—that are major contributions in the field. Several existing and new SRGMs are obtainable from these approaches.

UNIFIED MODELING APPROACH

Unified Scheme Based on the Concept of Infinite Server Queue

Assuming immediate repair action, FD&FC can be viewed as an infinite server queue (ISQ). Inoue and Yamada [62] first applied this concept to delayed S-shaped SRGM [17] and, by considering the time distribution of the fault isolation (successive to detection) process, obtained several NHPP models. Here, no consideration is made for the FC phenomenon. The approach in Ref. 60 is based on the basic assumptions of an SRGM defining the three levels of fault complexity [36]. An observed failure forms an arrival process. The number of failures observed at the end of testing period is equivalent to number of customers in the $M^*/G/\infty$ queueing system, where the arrival process (M^*) is an NHPP and service time has a general distribution (G). The MVF for failures process is $m_f(t)$ [$m_{fi}(t)$ for type i fault $i = 1, 2, 3$ (complex, hard, and simple)] and the intensity function $\lambda(t)$ ($\lambda_i(t)$ for type i fault $i = 1, 2, 3$).

For Complex Faults. For these faults, fault isolation (FI) follows detection, which is followed by removal. Fault isolation and removal times are assumed to be independent, with a common distribution $F_1(t)$ and $G_1(t)$, respectively. Let the counting processes $\{X_1(t), t \geq 0\}$, $\{R_1(t), t \geq 0\}$, $\{N_1(t), t \geq 0\}$ represent the cumulative number of failures, faults isolated, and faults removed, respectively, up to time t .

For Hard Faults. It is assumed that fault isolation follows immediately after failure observation with no delay. Fault detection and removal times are independent common distribution $G_2(t)$ and unit function, respectively. Let the counting processes $\{X_2(t), t \geq 0\}$, $\{N_2(t), t \geq 0\}$ represents cumulative observed software failure number and the faults isolated/removed, respectively, up to time t .

For Simple Faults. It is assumed that the faults are removed as soon as they are observed. Let $\{X_3(t), t \geq 0\}$, $\{N_3(t), t \geq 0\}$ be the counting processes that represent the cumulative number of software failure observed and removed, respectively, up to time t .

Assuming that the test began at time $t = 0$, the distribution of $N_i(t)$; $i = 1, 2, 3$ is given by

$$\Pr\{N_i(t) = n\} = \sum_{j=0}^{\infty} \Pr\{N_i(t) = n | X_i(t) = j\} \times \left((m_{fi}(t))^j e^{-m_{fi}(t)} / j! \right). \quad (22)$$

If j failures are observed, then the probability that n faults are removed is given as

$$\begin{aligned} \Pr\{N_i(t) = n | X_i(t) = j\} \\ = \binom{j}{n} (p_i(t))^n (1 - p_i(t))^{j-n}; \\ i = 1, 2, 3, \end{aligned} \quad (23)$$

where $p_i(t)$ is the probability that an arbitrary fault is removed by time t , which is defined using Stieltjes convolution, and concept of the

conditional distribution of arrival times as

$$\begin{aligned} p_1(t) = \int_0^t \int_0^{t-u} G_1(t-u-v) dF_1(u) \\ \times (dm_{fi}(v)/m_{fi}(t)) \end{aligned} \quad (24)$$

$$p_2(t) = \int_0^t G_2(t-u) (dm_{f2}(v)/m_{f2}(t)) \quad (25)$$

$$p_3(t) = \int_0^t 1(t-u) (dm_{f3}(v)/m_{f3}(t)), \quad (26)$$

where $1(\cdot)$ is the unit function. Hence,

$\Pr\{N_1(t) = n\} = m_1(t)^n e^{-m_1(t)} / n!$, where

$$\begin{aligned} m_1(t) = \int_0^t \int_0^{t-u} G_1(t-u-v) dF_1(u) \\ \times dm_{fi}(v) \end{aligned} \quad (27)$$

$\Pr\{N_2(t) = n\} = (m_2(t))^n (e^{-m_2(t)} / n!)$, where

$$m_2(t) = \int_0^t G_2(t-u) dm_{f2}(u), \quad (28)$$

$\Pr\{N_3(t) = n\} = (m_3(t))^n (e^{-m_3(t)} / n!)$, where

$$m_3(t) = \int_0^t 1(t-u) dm_{f3}(u) = m_{f3}(t). \quad (29)$$

Equations (27), (28), and (29) imply $N_1(t), N_2(t), N_3(t) \sim \text{NHPP}$ with MVF $m_1(t), m_2(t), m_3(t)$, respectively. Knowing the MVF $m_{f1}(\cdot), m_{f2}(\cdot), m_{f3}(\cdot)$ and distributions $F_1(\cdot), G_1(\cdot)$, and $G_2(\cdot)$, the MVF of one-, two-, and three-stage FD&FC processes for various existing SRGMs can be derived. Now, if $\{N(t), t \geq 0\}$ is the counting processes that represent the cumulative number of software fault removal up to time t , then $N(t)$ is derived as $N(t) = N_1(t) + N_2(t) + N_3(t)$, that is,

$$\begin{aligned} N(t) = ((m_1(t) + m_2(t) + m_3(t))^n / n!) \\ \times e^{-[m_1(t) + m_2(t) + m_3(t)]}. \end{aligned} \quad (30)$$

Hence

$$m(t) = m_1(t) + m_2(t) + m_3(t). \quad (31)$$

Obtaining SRGM from the Unified Model based on Infinite Queues. Assuming $m_{fi}(t) = \alpha_i(1 - e(-b_i t))$, $i = 1, 2, 3$, $F_1(t) = 1 - e(-b_1 t)$ and $G_i(t) = 1 - e(-b_i t)$, $i = 1, 2$, $m_i(t)$, $i = 1, 2, 3$ describe the MVF of Erlang SRGM [36] for complex, hard, and simple faults. Using Equation (31), the MVF of the total FC process of this model is obtained. Similarly, we can describe various existing and new SRGMs from this UM approach [60].

Unification Describing MVF from Failure Distribution under Imperfect Debugging

Under this approach [61], the intensity function is expressed as

$$\lambda(t) = m'(t) = (a(t) - m(t)) p(F'(t)/1 - F(t)), \quad (32)$$

where the total number of faults present at any testing time, say $a(t)$, is a function of time and can be expressed as a linear function of the expected number of faults detected by time t , that is,

$$a(t) = a + \alpha m(t),$$

hence

$$m(t) = (a/1 - \alpha) \left[1 - (1 - F(t))^{p(1-\alpha)} \right]. \quad (33)$$

Equation (33) assumes immediate removal of faults on failure observation.

To incorporate the concept of the FD&FC process with a delay, the above scheme is further generalized with the two distribution functions $F(t)$ (for FD) and $G(t)$ (for FC). The failure intensity function is now expressed as

$$\lambda(t) = m'(t) = ((f \times g)(t)/(1 - (F \otimes G)(t))) \times p(a + \alpha m(t) - m(t)). \quad (34)$$

Equation (34) implies

$$m(t) = (a/1 - \alpha) \left[1 - (1 - (F \otimes G)(t))^{p(1-\alpha)} \right]. \quad (35)$$

Using the generalized schemes (Eqs 33 and 35), the MVF of several existing and new SRGMs can be obtained from different distributions $F(\cdot)$ and $G(\cdot)$.

Obtaining SRGM from the Unified Model Describing MVF by Failure Distribution under Imperfect Debugging. If we assume $F(t) = 1 - e^{-bt}$, then Equation (33) yields the [63] SRGM defining two types of imperfect debugging:

$$m(t) = (a/1 - \alpha)[1 - e(-bp(1 - \alpha)t)]. \quad (36)$$

If we assume $F(t) = 1 - e^{-bt}$ and $G(t) = 1 - e^{-bt}$, the Yamada delayed S-shaped model is obtained under two types of imperfect debugging, that is,

$$m(t) = (a/1 - \alpha) \left[1 - ((1 + bt)e(-bt))^{p(1-\alpha)} \right]. \quad (37)$$

Similarly, for distinct distribution functions $F(t)$ and $G(t)$, a wide range of models were obtained.

Kapur *et al.* [63] have also shown that the above two unified approaches, as well as that due to Xie *et al.* [50] based on FD&FC processes, are theoretically equivalent. Kapur *et al.* [64–66] have also proposed various other unification schemes in order to unify the study of other SRGMs based on distinct assumptions such as unified scheme for SDE-based SR modeling with respect to time and test effort and unified scheme for change point concept models.

Starting from the beginning, we have described various SRGMs. SRGMs find many practical applications. For example, they are used to develop test cases, schedule status, and resource optimization; to count the number of faults remaining in the software; and to estimate and predict the reliability of the software during testing and in the operational environment. Application of a model for any particular application involves first selecting some appropriate models. For any general testing environment, selection of an appropriate model is a difficult task and requires considerable effort. No one has succeeded in identifying *a priori* the characteristics of software that will ensure that a particular model can be trusted for reliability predictions [67]. Most of the tools and techniques use *trend exhibited by the data* criterion for model selection. Among the tools that rank models is the AT&T software reliability engineering toolkit. This

tool can be used only for a few software reliability growth models. Asad *et al.* [67] discussed some criteria to choose the best model; however, their findings still cannot be considered general. Application of neural network-based approaches and unification schemes provide some solution to this problem. However, a study that can justify the selection of an appropriate model for any software project is still to be done. Once some representative set of models is selected, the next step involves estimating the unknown parameter of the models from the collected failure data. Method of maximum likelihood estimate (MLE) and nonlinear least squares are the two most important and widely used estimation techniques. The third step for the application is to establish the best model applicable to the situation under consideration. This step involves two parts: The first one is comparing the estimation results of the selected models. Various criteria are used to measure the goodness of fit such as mean square error (MSE), bias, coefficient of multiple determination (R^2), Chi-square test, root mean square prediction error (RMSPE), and so on. The second part involves establishing the predictive power of the models by estimating the parameters on the truncated data and predicting it over the remaining. Relative prediction error (RPE) is used to compare these results. Most of the NHPP models are nonlinear in nature and it is difficult to manually obtain the unknown model parameters. Statistical software packages such as SPSS, SAS, Mathematica, and so on. can be used to easily obtain the model parameters with high accuracy levels (details of actual failure datasets and estimation in Refs 1–3). In the next section, we describe some OR applications of these models.

USING SRGM FOR OPTIMIZATION

SRGMs are used at many decision making points in SDP, such as software release time (SRT) determination, resource allocation (RA) and control, optimum component selection for fault tolerant software, and so on. Here, we will highlight mainly two types of OR applications, namely, SRT determination and RA, for unit testing of modular software.

Software Release Time Determination

However important achieving high reliability of software may be, no software can be tested indefinitely and made fault free. Software user requirements are often conflicting with the developer requirements, as the former want faster deliveries, low-cost, and quality products, whereas the latter want to minimize their cost and maximize profit margins meeting competitive requirements. A crucial decision problem that arises here is to know when to stop testing and release the software to the user, which is known as the SRT problem. Delayed release results in penalties, revenue and goodwill loss, and obsolescence for the developers, while a premature release may cost high maintenance and goodwill loss cost during field use. The wealth of research in the area is impressive and confirms its continuing importance as a research topic. The SRT problem became the prime area of concern among researchers around 1980. Most of the problems discussed in the literature have the objective to minimize cost of ST&D during testing and operational (T&O) phases or maximize reliability subject to budgetary constraint and/or the minimum desired reliability level to be achieved by the release time. Models that minimize the number of remaining faults or the failure intensity also fall under this category.

The first attempt in determining SRT seems to have been made by Okumoto and Goel [68], who considered unconstrained problems using the GO model to describe the FD and/or FC processes. The cost function is defined for FI&FC during T&O phases (C_1 and C_2) and cost of testing per unit time (C_3), given as

$$C(T) = C_1 m(T) + C_2 (m(T_1) - m(T)) + C_3 T, \quad (38)$$

where T is the release time. The optimal SRT is determined by minimizing the cost function using the principles of calculus. The authors have also determined SRT such that the reliability $R(x|T)$ reaches a desired level (R_0) irrespective of the cost.

A significant contribution was made by Yamada and Osaki [69], who carried a trade-off between cost and reliability. Two

problems were discussed on the basis of two exponential and one flexible SRGM [13,16,17], the first minimizing the cost subject to reliability aspiration and the second maximizing reliability subject to cost not exceeding a predefined budget C_B , that is,

Case 1. Minimize $C(T)$ subject to $R(x|T) \geq R_0$.

Case 2. Maximize $R(x|T)$ subject to $C(T) \leq C_B$.

Kapur and Garg [70] introduced the concept of releasing the software at the scheduled delivery time for which a penalty cost $C_p(t)$ in $(0, t]$ due to delay is added to the cost function (38), that is,

$$C(T) = C_1 m(T) + C_2 (m(T_L) - m(T)) + C_3 T + \int_0^T C_p(T-t) dG(t). \quad (39)$$

The SRT problem of cost minimization subject to reliability aspiration was studied on three SRGMs [13,16,17]. Kapur and Garg [71] proposed the use of a test-effort-dependent SRGM to release problems, as resources decrease during the testing life-cycle so that the cumulative testing effort approaches a finite limit. Optimal release policies are discussed by maximizing the expected gain simultaneously achieving a given level of failure intensity. Mathematically, the SRT problem with gain maximization is stated as

$$\begin{aligned} \max G(T) &= (C_2 - C_1)m(T) - C_3 W(T) \\ \text{subject to } \lambda(T) &\leq \lambda_0. \end{aligned} \quad (40)$$

Yun and Bhai [72] proposed that it is more appropriate to assume random software life-cycle accounting to alternative competitive product and better releases by the developers. They defined the unconstrained problem of maximizing the total average profit with random life-cycle solving numerically using the bisection method again for exponential and flexible SRGM. Kapur *et al.* [73] reconsidered random life-cycle by defining policies on the basis of cost minimization subject to failure

intensity aspiration. Assuming $h(t)$, $H(t)$, and $r(t)$ to be the pdf, cdf, and hazard rate of the software life-cycle length, the expected total cost is defined as

$$\begin{aligned} C(T) &= C_1 \int_0^T m(t)h(t) dt + C_3 \int_0^T th(t) dt \\ &\quad + C_1 \int_T^\infty m(T)h(t) dt + C_3 T \bar{H}(T) \\ &\quad + C_2 \int_T^\infty (m(t) - m(T))h(t) dt. \end{aligned} \quad (41)$$

In the early 1990s, Kapur and Garg [74] made an initial attempt in determining SRT based on imperfect debugging SRGM by minimizing cost subject to reliability aspiration constraint. The cost function was modified to include separate cost of fixings due to perfect and imperfect debugging during T&O phases. They defined the cost function as

$$\begin{aligned} C(T) &= (C_1 p + C'_1(1-p))m_f(T) \\ &\quad + (C_2 p + C'_2(1-p))(m_f(\infty) - m_f(T)) \\ &\quad + C_3 T. \end{aligned} \quad (42)$$

Kapur and Garg [20] modified the cost model (Eq. 38) to incorporate the cost of removal of dependent faults ($\hat{C}_1, \hat{C}_2$) with the cost of independent faults and formulated the SRT problem based on the cost-reliability criterion. The modified cost model is

$$\begin{aligned} C(T) &= C_1 m_f(T) + \hat{C}_1 (m_f(T) - m_r(T)) \\ &\quad + C_2 (m_f(T_L) - m_f(T)) + \hat{C}_2 (m_r(T_1) \\ &\quad - m_r(T) - (m_f(T_1) - m_f(T))) + C_3 T, \end{aligned} \quad (43)$$

where T_L is the software life-cycle.

Kapur *et al.* [75] proposed a test-effort-based discrete exponential model and for the first time discussed release policies minimizing cost with failure intensity aspiration constraint for discrete SRGM. Further, Kapur *et al.* [76] brought the bi criterion release time optimization into this area carrying a trade-off between cost minimization and reliability maximization subject to budget and reliability aspiration constraints for both

exponential and flexible SRGM. The problem is stated as

$$\begin{aligned}
& \text{Maximize} && R(x/T) \text{ (or } \log R(x/T)); \\
& \text{Minimize} && C(T) \text{ (or } \bar{C}(T)) \\
& \text{s.t.} && C(T) \leq C_B \text{ (or } \bar{C}(T) \leq 1); \\
& && R(x/t) \geq R_0 \quad T \geq 0; \\
& && 0 < R_0 < 1; \quad \bar{C}_T = C_T/C_B.
\end{aligned}$$

The problem is transformed to single objective using scalarization with the parameter $\lambda = \lambda_i, i = 1, 2; \lambda_1 + \lambda_2 = 1$. Such a release policy gives enough flexibility to the developers based on their priority in respect of reliability and cost components. For safety-critical projects, a higher weight ($\lambda_1 > \lambda_2$) may be attached to the reliability objective, whereas for product type more weight may be attached to the cost objective ($\lambda_2 > \lambda_1$).

Pham [77] proposed an SRGM for three-level fault complexity considering fault generation and studied release policies on this model (minimizing cost subject to reliability aspiration or maximizing reliability subject to cost constraint) incorporating penalty cost and random life-cycle in the cost function along with traditional costs. The cost model is given as

$$\begin{aligned}
C(T) = & \sum_{i=1}^3 C_{i1} m_i(T) \\
& + \int_T^\infty \left(\sum_{i=1}^3 C_{i2} (m_i(t) - m_i(T)) \right) g(t) dt \\
& + C_3 T + I(T - T_d) C_p (T - T_d), \quad (44)
\end{aligned}$$

where i denote the fault complexity level in costs C_1 and C_2 , $g(t)$ is the pdf of the life-cycle length, and $I(t)$ is an indicator function. A major contribution was made by Pham and Zhang [78], who modified the cost function incorporating warranty, risk, and correction time costs and carried unconstrained cost minimization to compute SRT. The modified function is defined as

$$\begin{aligned}
C(T) = & C_1 m(T) \mu_y + C_2 \mu_w (m(T + T_w) \\
& - m(T)) + C_3 T^\alpha + C_4 (1 - R(x|T)), \quad (45)
\end{aligned}$$

where μ_y and μ_w are the expected time to remove faults upto time T and during the warranty period, respectively, the per-unit testing time cost is taken as a power function of time T to consider the higher increases in the beginning and slow down later, and the last term denotes the risk cost.

Xie [79] studied the release policies for IFR SRGM [29] though he referred to it as *error generation SRGM* [30]. The author proposed that the cost of testing C_3 is a function of perfect debugging probability p because, if this probability is to be increased, more resources are required, which will result in an increase in C_3 . The modified cost model is given as

$$\begin{aligned}
C(T) = & C_1 m(T) + C_2 (m(\infty) - m(T)) \\
& + (C_3 / (1 - p)) T \quad (46)
\end{aligned}$$

Pham and Zang [80] studied release policies by minimizing the cost subject to reliability requirement for a test-coverage-based SRGM assuming that a risk cost is associated with uncovered code $(1 - C(T))$ remaining at the release time which is to be paid to each user (D in number). The cost model was defined as

$$C(T) = C_1 m(T) \mu_y + C_3 T + C_3 D (1 - C(T)). \quad (47)$$

Kapur *et al.* [81] modified the cost model in Ref. 79 by incorporating a separate cost of fixing due to perfect and imperfect fault debugging during T&O phases. The cost model is

$$\begin{aligned}
C(T, p) = & (C_1 p + C'_1 (1 - p)) m_f(T) \\
& + (C_2 p + C'_2 (1 - p)) (m_f(\infty) - m_f(T)) \\
& + C_3 T / (1 - p). \quad (48)
\end{aligned}$$

They also integrated the effect of two types of imperfect debugging in an exponential SRGM and modified the cost model such that the testing cost per unit testing time is taken as a function of both the probability of perfect debugging p and error generation α . Release policies minimizing cost under the reliability aspiration were considered. Gupta *et al.* [82] have also formulated and solved these policies in

discrete-times. Apart from these, many other RT studies have been described in the literature, most of them being formulated on distinct SRGMs but the major concepts remaining the same as discussed above.

Resource Allocation for Unit Testing of Modular Software

Software testing process involves three successive stages: module, integration, and system. Since the amount of available test resources is usually limited, maximum faults are removed in unit testing, which consumes almost 40–50% of total test resources, and it is very important to spend them judiciously and distribute optimally among the various modules so as to attain highest possible reliability by the release. Resource allocation problems have been studied extensively in the literature. Modules are considered independent during unit testing. Firstly, Ohetera and Yamada [83] considered two problems based on the GO model. One minimizes the mean number of remaining faults in M independent modules under the resource limitation constraint, that is,

$$\begin{aligned} \text{minimize} \quad & \sum_{i=1}^M v_i a_i e^{-b_i W_i} \\ \text{s.t.} \quad & \sum_{i=1}^M W_i = W, \quad W_i \geq 0. \end{aligned} \quad (49)$$

The second one minimizes the total resource expenditure assuming remaining fault number at the termination of module testing is Z , and is formulated as

$$\begin{aligned} \text{minimize} \quad & \sum_{i=1}^M W_i \\ \text{s.t.} \quad & \sum_{i=1}^M v_i a_i e^{-b_i W_i} = Z, \quad W_i \geq 0. \end{aligned} \quad (50)$$

Here, v_i is the weight assigned to the i th module and test effort is not taken as a function of time since testing is continued for a finite time period. Yamada *et al.* [84] further

incorporated SR aspiration in the problem. Lagrange's technique was used to solve the problems and numerical illustrations were provided.

Leung [85] reconsidered problems in Ref. 83 by dividing the total testing time into K testing periods. In each period, failure data is recorded and at the end of period model parameters, remaining fault number are re - estimated, and then the amount of resources for the next time period for each module is determined. Their problem can be stated as follows:

$$\begin{aligned} \text{Minimize} \quad & \sum_{i=1}^M v_i a_{ij} e^{-b_{ij} W_{ij}} \\ \text{s.t.} \quad & \sum_{i=1}^M W_{ij} = W_j, \quad W_{ij} \geq 0. \end{aligned} \quad (51)$$

The constraints ensure that the total resources allocated to all modules in j th period is W_j , where

$$W_j = ((T_{j+1} - T_j)/(T_{K+1} - T_1))W.$$

The author also considered the problem in Equation (50) in the same manner and used the Lagrange method to solve the problems.

Xie and Yang [86] discussed the allocation of the total testing time to each software module using the Lagrange technique such that operational failure intensity is minimum using the GO model formulated as

$$\begin{aligned} \text{minimize} \quad & \sum_{i=1}^M \lambda_i(T_i) \\ \text{s.t.} \quad & \sum_{i=1}^M T_i \leq T, \quad T_i \geq 0, \end{aligned} \quad (52)$$

where T_i is the testing time for module i and T is the total testing time. They also conducted a sensitivity analysis to determine which of the model parameters affects the system most.

Lyu and Moorsel [87] considered software consisting of M modules performing N applications. They defined the problem by minimizing the total testing time of modules such

that the sum of failure rates (λ_i) of the components (δ_i) in each application is less than a desired level ($\delta_j, j = 1, 2, \dots, N$). The problem is stated as

$$\begin{aligned} &\text{minimize } \sum_{i=1}^M T_i \quad \text{s.t.} \quad \sum_{i=1}^M \sigma_{j,i} \cdot \lambda_i \leq \delta_j; \\ &\delta_j, T_i, \lambda_i \geq 0; \quad i = 1, 2, \dots, M, \quad j = 1, 2, \dots, N \\ &\sigma_{j,i} = 1 \text{ if } A_j \text{ uses module } i; \quad 0 \text{ otherwise.} \end{aligned} \quad (53)$$

They also stated and solved the problem alternatively by minimizing the total failure intensity of modules such that the total testing time assigned to each application gets at most a specified amount (d_j), that is,

$$\begin{aligned} &\text{minimize } \sum_{i=1}^M \lambda_i \quad \text{s.t.} \quad \sum_{i=1}^M \sigma_{j,i} \cdot T_i \leq d_j; \\ &d_j, T_i, \lambda_i \geq 0; \quad i = 1, \dots, M, \quad j = 1, \dots, N. \end{aligned}$$

Huang *et al.* [88] formulated and solved three problems assigning weights to each modules based on Kuhn–Tucker conditions. The first minimizes the remaining number of faults subject to budget and reliability aspiration constraint; the second and third minimize the total resources and cost, respectively, subject to desired reliability and remaining fault level constraints. The problems are illustrated on a GO model with test efforts assuming a generalized logistic test effort function. All the previous problems have considered Weibull-type test effort functions. The cost model considered is

$$\begin{aligned} C(T) &= C_1 m(T) + C_2 (m(\infty) - m(T)) \\ &+ C_3 \int_0^T w(x) dx. \end{aligned}$$

Haung *et al.* [89] performed sensitivity analysis on the principal parameters of the models. Lo [90] performed sensitivity analysis [83] to determine which of the model parameters affect the system most.

Rajan and Misra [91] first formulated an unconstrained problem and determined the optimal number of tests needed to test each module in unit testing. Later, they also

included the budget constraint and solved the problem. All these allocation problems have been discussed on an exponential SRGM. Kapur *et al.* [92,93] and Jha *et al.* [94] studied various resource allocation problems maximizing the number of faults removed from each module under constraint on budget and/or management aspirations on reliability. They illustrated their problems by proposing a flexible SRGM incorporating test effort considering fault dependency, fault dependency and imperfect debugging, and testing coverage and debugging time lag. The problem is stated as

$$\begin{aligned} &\text{minimize } \sum_{i=1}^M m_i \\ &\text{s.t.} \quad \sum_{i=1}^M W_i = C_B, \quad W_i \geq 0. \end{aligned} \quad (54)$$

They have discussed dynamic, mathematical, and goal programming approaches to yield solutions of such classes of optimization problems.

The existing literature on SRGM well as optimization based on SRGM is very vast, all of which cannot be described here for the want of space.

CONTROL VARIATES

LOO HAY LEE

SHAO JIJUN

Department of Industrial and
Systems Engineering, National
University of Singapore

Control variates (CV), or *regression sampling*, is a widely used variance reduction technique (VRT) in Monte Carlo simulation. This method attempts to take advantage of the correlation between random variables to obtain a variance reduction. Depending on the actual problem and the parameter of interest, this correlation used in different CV techniques may be internally available during the course of the original simulation or externally generated using common random numbers (CRN) [1]. CV techniques are popular because of the ease of implementation, the availability of controls, and the straight intuition of the underlying theory [2].

BACKGROUND

When studying or analyzing a complicated system, or sometimes modeling a real-world problem, Monte Carlo simulation is one of the most commonly used methods. Owing to the randomness nature of Monte Carlo methods, the output from such simulation often contains a large amount of uncertainty. This uncertainty will affect the accuracy of the results when we want to draw conclusions about the underlying characteristics of the parameter of interest from the simulation model. Various techniques have been developed to tackle this problem. However, most of them would require many simulation replications, thus making the experiment costly and time consuming. In contrast, VRTs are often able to achieve higher statistical efficiency by reducing the variance of the output random variables without introducing substantial computing cost and bias in its expectation.

Unlike CRN, which is another common VRT often employed to compare two different system configurations, control variates are effective in analyzing a single system performance. Furthermore, CV techniques do not rely on the sign of the correlation; whereas CRN and antithetic variate (AV) both require the correlation being a particular sign (see **Common Random Numbers** and **Antithetic Variates**). As Nelson pointed out in his article “control variate remedies,” the CV method has several advantages comparing to other methods of variance reduction: “it is applicable in single or multiple response simulations; it does not require altering the simulation run; and any stochastic simulation contains potential control variates.” [3]

CLASSICAL CONTROL VARIATE TECHNIQUES

The CV technique is well established as a useful tool in general stochastic simulation experiments. It is applicable in any stochastic simulation, and applying CV technique to estimate one parameter would not conflict with estimating other parameters. [3]

A lot of work related to the CV technique can be found in the literature, ranging from estimating means, to estimating other performance measures in the model. The basic idea of control variates is to take advantage of correlation between certain random variables and to use variables with known properties to adjust, or “control,” the estimator of interest. The following example is an illustration of how a simple CV technique can be applied in a typical queueing model:

Example 1. Consider an M/M/1 queue, let X be an output random variable representing the average delay in the queue for the first 100 customers and we are interested in X 's expectation $\mu = E(X)$. We can define another random variable Y to be the average service time of the first 99 customers in the same queueing model. In a typical simulation experiment, the expected value of Y would be known to us since it is generated

from some input distributions. Furthermore, it is reasonable to argue that longer than average service times would lead to a longer than average waiting time and vice versa. In other words, if Y is larger than its known expectation, then the value of X would also be greater than its true expectation. It gives us some intuition to adjust the value of the estimator of $E(X)$ downwards, if we find Y is above its expectation. In this case, the variable Y could be used as a control variate for the estimator of $E(X)$, since we can adjust, or “control,” the value of the estimator according to the value of Y and its expectation. [1]

In the above example, the control variate Y is positively correlated with the output variable X whose expectation is of interest. However, the success of control variate techniques does not depend on the sign of the correlation. If we define variable Y as the average interarrival time for the first 100 customers, we will find that Y is negatively correlated with X , that is, when Y is above its expectation, the estimator of X should be smaller than its actual value. As a result, we could still use Y as a control variate for the estimator of $E(X)$, that is, we will adjust the value for the estimator of $E(X)$, upward when the value of Y is smaller than its expectation, and vice versa.

For this queueing problem, if n replications of simulations are performed, we could use $\bar{X}(n)$ to denote the sample average of variable X and $\bar{Y}(n)$ as the sample average of control variate Y obtained from the n simulation runs. Let the expected value of Y be denoted by v , which is known to us, that is, $v = E(Y)$. If $\bar{Y}(n)$ differs from its mean value v , we can adjust the value of the estimator X by using the following formula:

$$X_c = \bar{X}(n) - a [\bar{Y}(n) - v], \quad (1)$$

where X_c is the new estimator for X using Y as a control variate and a is the control coefficient. From the derivation below, we can conclude that the new estimator X_c is an

unbiased estimator of X .

$$\begin{aligned} E(X_c) &= E[\bar{X}(n)] - E\{a [\bar{Y}(n) - v]\} \\ &= E[\bar{X}(n)] - a \{E[\bar{Y}(n)] - v\} \\ &= E(X) = \mu. \end{aligned} \quad (2)$$

Its variance is given by

$$\text{Var}(X_c) = \text{Var}(X) + a^2 \text{Var}(Y) - 2a \text{Cov}(X, Y). \quad (3)$$

From Equation (3), we can see that the variance of the new estimator X_c is smaller than the variance of the original estimator X , if $a^2 \text{Var}(Y) < 2a \text{Cov}(X, Y)$. Hence if X and Y are positively correlated, there will be a variance reduction when the value of coefficient a is positive but smaller than $2\rho(X, Y) \frac{\sigma(X)}{\sigma(Y)}$; if X and Y are negatively correlated, the variance reduction exists when the value of a is negative and $|a| < |2\rho(X, Y) \frac{\sigma(X)}{\sigma(Y)}|$. The optimal choice of a can be found by finding the derivative of the right-hand side of Equation (3) and setting it to zero. The optimal value of coefficient a , denoted by a^* is given by

$$a^* = \frac{\text{Cov}(X, Y)}{\text{Var}(Y)} = \rho(X, Y) \frac{\sigma(X)}{\sigma(Y)}. \quad (4)$$

The variance of the optimal control variate estimator, denoted by X_c^* , can be expressed in the following equation:

$$\begin{aligned} \text{Var}(X_c^*) &= \text{Var}(X) - \frac{[\text{Cov}(X, Y)]^2}{\text{Var}(Y)} \\ &= [1 - \rho^2(X, Y)] \text{Var}(X). \end{aligned} \quad (5)$$

The maximum reduction in variance is thus $\rho^2(X, Y) \text{Var}(X)$. If $\rho \rightarrow \pm 1$, which means that X and Y are almost perfectly correlated, the variance of the control variate estimator would become very close to zero, indicating that we can get a very precise estimator for μ .

However, to compute the optimal coefficient a^* would require the value of the variance of the control variate Y and the covariance between X and Y . In the actual application, we may be able to find the variance of Y , since it is an input variable that is generated by us (in some other examples, we may not

be able to obtain this variance too), but it is nearly impossible for us to know the exact value of the covariance between X and Y . Thus, to use control variate techniques, we need to find a way to estimate these important parameters. Many methods have been proposed to estimate α^* , and one common method is to replace $\text{Var}(Y)$ and $\text{Cov}(X, Y)$ with their sample estimators. Thus, the covariance $\text{Cov}(X, Y)$ can be estimated by

$$\hat{C}_{XY}(n) = \frac{\sum_{j=1}^n [X_j - \bar{X}(n)] [Y_j - \bar{Y}(n)]}{n-1}, \quad (6)$$

where X_j and Y_j denote the individual response observed in simulation run j for variable X and Y , and $\hat{C}_{XY}(n)$ is the sample covariance estimated from n simulation replications. The variance of Y , $\text{Var}(Y)$ can also be estimated by the sample variance $S_Y^2(n)$

$$S_Y^2(n) = \frac{\sum_{j=1}^n [Y_j - \bar{Y}(n)]^2}{n-1}. \quad (7)$$

Using these two sample estimators of variance and covariance, we are able to estimate the optimal coefficient α^* by

$$\hat{\alpha}^*(n) = \frac{\hat{C}_{XY}(n)}{S_Y^2(n)}. \quad (8)$$

And the corresponding control variate estimator of μ is then given by $\hat{X}_C^*$

$$\hat{X}_C^* = \bar{X}(n) - \hat{\alpha}^*(n) [\bar{Y}(n) - v]. \quad (9)$$

Another property of the estimator $\hat{\alpha}^*(n)$ is that $\hat{\alpha}^*(n)$ is equal to the least square estimator of the regression coefficient α in the following simple linear regression equation:

$$X = \alpha Y + \beta + \varepsilon, \quad (10)$$

where ε denotes the stochastic disturbance around the regression line and α and β are the regression coefficients.

By definition, coefficient α minimizes the term $\sum_{i=1}^n (X_i - \tilde{X}_i)^2$, where X_i is the observed response from the i th simulation

replication and $\tilde{X}_i$ is the value predicted from the regression equation. Thus, it is equal to minimizing $\sum_{i=1}^n (X_i - \alpha Y_i - \beta)^2$ [4].

Since $\hat{\alpha}^*(n)$ is calculated from the same samples as the sample mean $\bar{Y}(n)$, they are dependent with each other. As a result, this new estimator $\hat{X}_C^*$ would possibly be biased, and the amount of variance reduction might be reduced as well.

To deal with this problem, there are a number of methods proposed by various researchers to find an unbiased control variate estimator. Tocher [5] mentioned in his book that by splitting all n observations (X_i, Y_i) into two groups with each group consisting of half of the observations, he is able to construct an unbiased estimator. From these two groups of data, two different estimators of the coefficient α , $\hat{\alpha}_1^*(\frac{n}{2})$ and $\hat{\alpha}_2^*(\frac{n}{2})$ can be obtained. It is then possible to construct two control variate estimators by combining $\hat{\alpha}_1^*(\frac{n}{2})$ with the second group of data and $\hat{\alpha}_2^*(\frac{n}{2})$ with the first group of data. An unbiased estimator can be obtained by averaging these two new control variate estimators.

Tocher also derived that the variance of the unbiased estimator is two times of the variance of the optimal estimator using α^* derived earlier. However, there is a remedy for this variance increase, that is, by utilizing generalized splitting. This method would require to divide the n pairs of observations into J groups ($2 < J \leq n$), and the estimator of the coefficient of group j is derived using all observations except the observations belonging to group j . Using the same method as in the two group case, a more effective variance reduction is obtained from this new estimator.

Another widely used bias reduction technique is Jackknifing technique. Lavenberg *et al.* [6] discussed how to use Jackknifing technique to estimate the confidence interval for some closed queueing networks.

GENERALIZATION ON BASIC CV TECHNIQUES

The discussion presented above mainly focuses on using a single control variate. We

shall then discuss some generalization of this basic CV technique.

In a simulation experiment, it is common that we are able to find not only a single “control variable”, but several other variables suitable of being used as control variates. As we discussed in the previous example, both average customer interarrival time and customer service time can be used as control variates. Under such a case, we could then formulate a kind of “multiple” control variate estimator using m different control variates $Y_i, i = 1, 2, \dots, m$, as follows:

$$X_{cm} = \bar{X}(n) - \sum_{i=1}^m a_i (\bar{Y}_i(n) - v_i), \quad (11)$$

where $\bar{Y}_i(n)$ is the sample average of the simulation response for the i th control variate, and v_i is the known expectation for Y_i . All a_i 's are the coefficients which need to be estimated. It will be more convenient to consider control variates with zero-expectation, and so Kleijnen [4] redefine the control variates Z_i for each Y_i as follows:

$$Z_i = \bar{Y}_i(n) - v_i, \quad i = 1, 2, \dots, m. \quad (12)$$

It is clear that $E(Z_i) = 0$, and the control variate estimator defined in Equation (11) is then

$$X_{cm} = \bar{X}(n) - \sum_{i=1}^m a_i Z_i. \quad (13)$$

If the control variates $Z_i (i = 1, 2, \dots, m)$ are all independent with each other, which will be the case if we assume that all Y_i s are input variables, the variance of the new estimator X_{cm} is then

$$\begin{aligned} \text{Var}(X_{cm}) &= \text{Var}[\bar{X}(n)] - \sum_{i=1}^m a_i^2 \text{Var}(Z_i) \\ &\quad - 2 \sum_{i=1}^m a_i \text{Cov}(X, Z_i). \end{aligned} \quad (14)$$

Taking partial derivatives of the right-hand side of Equation (14) with respect to each of the a_i s and equating them to zero, we can

find the optimal values for a_i s. The optimal values are

$$a_i^* = \frac{\text{Cov}(X, Z_i)}{\text{Var}(Z_i)}. \quad (15)$$

Using the fact that $E(Z_i) = 0$, we can have a simple estimator of the optimal control coefficient

$$\hat{a}_i^* = \frac{\sum_{j=1}^n X_j Z_{ij}}{\sum_{j=1}^n Z_{ij}^2}, \quad \text{where } i = 1, 2, \dots, m. \quad (16)$$

In Equation (16), X_j is the observation from j th simulation run, and Z_{ij} is the value calculated using $Y_{ij} - v_i$, while Y_{ij} is the observation of variable Y_i in j th run.

We can also show that this estimator is equivalent to the least square estimators of the regression coefficients of the following equation:

$$X_j = \sum_{i=1}^m a_i Z_{ij} + \varepsilon_j, \quad \text{where } j = 1, 2, \dots, n. \quad (17)$$

Lavenberg and Welch [7], as well as Nelson [3], both discussed the case where correlation between control variates $Z_i (i = 1, 2, \dots, m)$ are allowed. Under the assumption that the random output X and the m control variates $Z_i (i = 1, 2, \dots, m)$ follow multivariate normal distribution, it turns out that the optimal variance minimizing coefficients are identical to least-square estimates of the coefficients in a linear-regression model. This is the reason why CV is often referred to as *regression sampling*.

In the queueing model in Example 1, the control variate Y is defined as the average service time of the first 99 customers. In a typical simulation experiment, since the service time of each customer is an input variable and is generated from some given distribution, we can also define the service time of these 99 individual customers as 99 i.i.d random variables. In this way, the control variate Y can be seen as a function (simple average) of these 99 i.i.d input random variables. Similarly, we can also define Y as some

other more complicated function of the individual input variables which are generated from some known input distribution [4]. We define the new control variate Z , as follows:

$$Z = g[Y(1), Y(2), \dots, Y(m)], \quad (18)$$

where g is a function of the m individual input variables $Y(1), Y(2), \dots, Y(m)$ in a single simulation run. For example, in a single server queue similar to the one described above, $Y(1)$ is the service time for the first customer, $Y(2)$ is the service time for the second customer, and $Y(m)$ is the service time for the m th customer. These m random variables are used in the simulation as inputs and are generated using a known distribution. The function g is a general function which could include higher order terms of $Y(i)$ s, some ratio terms, or even terms which requires maximizing or minimizing of some function of the variable $Y(i)$ s [8]. And the number of inputs, m , can also be stochastic. Take a single server queue as an example, if we simulate for a given amount of time, say, t , then because the number of customers in a given time period is random, the number of service times generated for the customers in a single simulation run is also random.

The new variable Z can be seen as a function of the m responses for a stochastic input variable Y . We need to impose an additional condition that the expected value of Z can be obtained. Thus,

$$E(Z) = E\{g[Y(1), Y(2), \dots, Y(m)]\} = \xi. \quad (19)$$

And we can get the new control variate estimator X_{cg} by

$$X_{cg} = \bar{X}(n) - Z + E(Z) = \bar{X}(n) - g[Y(1), Y(2), \dots, Y(m)] + \xi. \quad (20)$$

The expected value and variance of X_{cg} is given by

$$\begin{aligned} E(X_{cg}) &= E[\bar{X}(n)] - E(Z) + \xi \\ &= E[\bar{X}(n)] - \xi + \xi = E(X) \end{aligned} \quad (21)$$

$$\text{Var}(X_{cg}) = \text{Var}[\bar{X}(n)] + \text{Var}(Z) - 2\text{Cov}(X, Z). \quad (22)$$

From Equation (22) we can see that different from all previously discussed control variates, in this case, the control variate Z should be constructed such that it would have a “strong” positive correlation with the parameter of interest X . Considering a general definition where the number of responses, m , is stochastic, Z can be defined as follows:

$$\begin{aligned} Z &= g[Y(1), Y(2), \dots, Y(m)] \\ &= b_1 + b_2 \sum_{i=1}^m Y(i) + b_3 \left[\sum_{i=1}^m Y(i) \right]^2, \end{aligned} \quad (23)$$

Then the control variate estimator using the above defined Z can be written as

$$\begin{aligned} X_{cg2} &= \bar{X}(n) \\ &\quad - \left\{ b_1 + b_2 \sum_{i=1}^m Y(i) + b_3 \left[\sum_{i=1}^m Y(i) \right]^2 \right\} \\ &\quad + E \left\{ b_1 + b_2 \sum_{i=1}^m Y(i) + b_3 \left[\sum_{i=1}^m Y(i) \right]^2 \right\} \\ &= \bar{X}(n) - b_2 \left\{ \sum_{i=1}^m Y(i) - E \left[\sum_{i=1}^m Y(i) \right] \right\} \\ &\quad - b_3 \left\{ \left[\sum_{i=1}^m Y(i) \right]^2 - E \left\{ \left[\sum_{i=1}^m Y(i) \right]^2 \right\} \right\}. \end{aligned} \quad (24)$$

Since

$$E \left[\sum_{i=1}^m Y(i) \right] = vE(m) \quad (25)$$

$$E \left\{ \left[\sum_{i=1}^m Y(i) \right]^2 \right\} = v^2 E(m^2) + \sigma^2 E(m), \quad (26)$$

where $v = E[Y(i)]$ and $\sigma^2 = \text{Var}[Y(i)]$. Since all $Y(i)$ s are generated from some given input distribution, v and σ^2 can be obtained easily. Then, if we can calculate the expected value of the number of responses, we are able to use Equation (24). Otherwise, if we are unable to obtain these expectations, we can replace X_{cg2}

by the following control variate estimator:

$$X_{c_{g3}} = \bar{X}(n) - b_2 \left[\sum_{i=1}^m Y(i) - vm \right] - b_3 \left\{ \left[\sum_{i=1}^m Y(i) \right]^2 - (v^2 m^2 + \sigma^2 m) \right\}. \quad (27)$$

We can see that Equation (27) is an unbiased estimator. Thus, it is suitable for us to run the simulation, obtain the value of v and m at the end of the experiment, and then use Equation (27) as a control variate estimator to estimate the parameter of interest [4].

SELECTING THE BEST CONTROL VARIATES

In most simulation experiments, the optimal control variate coefficient can only be estimated. While we have discussed several ways to estimate the coefficient in the above section, we should note that such estimation may introduce extra variance, thus offsetting the variance reduction obtained from using control variates, especially when using multiple control variates. In previous discussions, we can see that the number of control variates available for a given simulation experiment may be quite large. Simply using all the available control variates may increase the overall cost, and more importantly, reduce the variance reduction we want to achieve. Thus, it is intuitive that we may want to only select a subset of these available control variates to maximize the variance reduction and avoid biasness in the estimators. Bauer and Wilson [9], in their paper, proposed control-variate selection criteria, which minimize the mean-square confidence-region volume.

Let us define the following terms to be used in this section. We use $\mathbf{X} = [x_1, x_2, \dots, x_p]'$ to denote a column vector representing p responses of interest generated on the simulation experiment, with $\mu_X = E(\mathbf{X})$ to be estimated. The pool of m control variates is denoted by another column vector $\mathbf{Y} = [Y_1, Y_2, \dots, Y_m]'$ with m columns and known mean $\mu_Y = E(\mathbf{Y})$. Thus, if we use a $q \times m$ matrix α to denote the control variate coefficient, the

controlled response can be written as

$$\mathbf{X}_c = \mathbf{X} - \alpha (\mathbf{Y} - \mu_Y). \quad (28)$$

This control variate estimator is an unbiased estimator of the response $\mathbf{X}$, and its variance can be minimized with optimal value of α , given by

$$\alpha^* = \Sigma_{XY} \Sigma_Y^{-1}, \quad (29)$$

where Σ_{XY} represents the covariance matrix between $\mathbf{X}$ and $\mathbf{Y}$, while Σ_Y denotes the covariance matrix of $\mathbf{Y}$. As it is often the case that we do not know the covariance between $\mathbf{X}$ and $\mathbf{Y}$, this optimal value α^* needs to be estimated by

$$\hat{\alpha}^* = \mathbf{S}_{XY} \mathbf{S}_Y^{-1}. \quad (30)$$

In Bauer and Wilson's paper, a control variate selection criterion is proposed based on the principle of minimizing the mean square volume of the confidence region. In order to present this criterion clearly, additional notation is defined. We define a nonnegative integer r to denote the number of control variate candidates currently under consideration, and $u(m, r) \equiv \frac{m!}{r!(m-r)!}$ to represent the total number of distinct control variate subsets of size r . We define $I(h, r)$, with $h = 1, 2, \dots, u(m, r)$, to denote the h th distinct subset of size r . On the j th run of the simulation model, we use $\mathbf{Y}_{(j)}(h, r) \equiv (Y_{(j)i_1}, Y_{(j)i_2}, \dots, Y_{(j)i_r})'$, where $\{i_1, i_2, \dots, i_r\} = I(h, r)$ to denote the r -dimensional vector of controls corresponding to the index set $I(h, r)$. Similarly, we define $\hat{\Sigma}_{X|Y}(h, r)$ to be the estimator of the conditional covariance matrix of $\mathbf{X}$ given $\mathbf{Y}$, when the control variate vector $\mathbf{Y}(h, r)$ defined by $I(h, r)$ is used. Then the best selection is obtained by minimizing the following expression:

$$\min_{\substack{0 \leq r \leq m \\ 1 \leq h \leq u(m, r)}} \left\{ \frac{|\hat{\Sigma}_{X|Y}(h, r)| \Gamma\left(\frac{n}{2}\right)}{\left[\left(\frac{p}{2}\right) \Gamma\left(\frac{p}{2}\right)\right]^2 \Gamma\left[\frac{n-2p}{2}\right]} \times \left[\frac{2\pi p F_{1-\alpha}(p, n-r-p)}{n(n-r-p)} \right]^p \times \prod_{i=1}^p \left(\frac{n-r-1}{n-r-2i} \right) \right\}, \quad (31)$$

where $F_{1-\alpha}(p, n - r - p)$ denotes the quantile of order $1 - \alpha$ for a F distribution with p and $n - r - p$ degrees of freedom.

As this optimization problem is not easy to solve when the number of available controls become very large, Bauer and Wilson [9] suggested using the method in a stepwise fashion to select some “good” controls instead of finding the optimal ones. For a more detailed explanation and derivation, please refer to Bauer and Wilson’s paper.

ADVANCED NEW DEVELOPMENT IN CV TECHNIQUES

More recently, many new methods of applying CV techniques in different problems have been proposed by researchers. Nelson [3] reviewed some popular control variate techniques in the literature. By considering small sample statistical properties, he conducted systematic analytical and empirical evaluation on these techniques. Szechtman [2] presented a comprehensive review of classical control variate techniques, focusing on both theory and application.

Glynn and Whitt [10] showed that, the asymptotic efficiency of any nonlinear control variates is the same as that of a linear control variate scheme under mild conditions. Porta Nova and Wilson [11] studied methods to develop control variates for multiresponse simulation metamodels. In their study, both the input and output of the metamodels could be multidimensional. As a result, the control variates can be applied to multipopulation, multiresponse simulation experiments. Nelson and Hsu [12] introduced control-variate models of CRN that permit exact statistical inference, specifically for comparing more than two systems. These models explain the effect of CRN via a linear regression of the simulation output on control variates that are functions of the simulation inputs. Rubinstein and Marcus [13] analytically derived the optimal size of the control variate vector under specific assumptions on the covariance matrix. To effectively measure the efficiency of the control variate technique, Venkatraman and Wilson [14] studied ways to measure the efficiency of the control variate technique effectively. They proposed a simplified

formulation of the variance ratio and a loss factor to evaluate the trade-offs in selecting control variates for a simulation experiment.

The effectiveness of the CV technique largely depends on the covariance between the control variates and the parameter of interest. To increase this covariance and thus, to improve the performance of the control variate, different forms of parametric transformations including polynomial transformations, the Box–Cox family of power transformations, and the inverse-normal probability transformation could be used on the linear control variates discussed earlier. Besides these classical approaches, Swain [15] considered a form of nonparametric transformations using natural cubic splines which provide a virtually unrestricted source of transformations, with considerable flexibility at the expense of additional computational effort. A nonlinear regression problem was analyzed to illustrate this transformation methodology.

Classical control variate techniques require that users know the means of the controls. Borogovas and Vakili [16] relaxed this requirement and allow the means to be estimated. They analyzed the properties of controlled estimators, and proposed a class of controls in a parametric estimation setting. Wieland and Schmeiser [17] investigated a case where the variance of the control variate is known, but the covariance between the control variate and the parameter of interest is unknown. A mixed estimator, which uses an estimate of the correlation of the performance measure and the control variate is evaluated. Their results indicated that the mixed estimator had most potential benefit when no information on the correlation is available, especially when sample sizes are small. Kim and Henderson [18] studied the case of finite-horizon simulation when nonlinearly parameterized control variables are available. They developed two adaptive control variate methods based on stochastic approximation and sample average approximation. They also provided conditions under which the adaptive estimators are consistent. Henderson and Glynn [19] discussed control variate application in Markov process simulation. They proposed a new approach

to construct a martingale as an internal control variate. Maire [20] presented a variance reduction method for Monte Carlo integration based on an iterated computation of L2 approximations using control variates. In his results, Monte Carlo estimates with increased convergence rate are obtained for mono-dimensional integrals of regular functions using only sample values.

APPLICATIONS OF CV TECHNIQUES

Control variate techniques can be easily applied to queueing systems, truck dock systems and many other simulation systems [4]. Quite recently, a number of control variate applications in stock and option pricing are proposed by different researchers. Glasserman [21] gave many examples on the application of control variates in various option pricing problems. Pellizzari [22] proposed a new control variate technique and a general Monte Carlo procedure. This technique could be used on a variety of multifactor options. Bolia and Juneja [23] presented a zero-variance or “perfect” control variate to price American options. They also explained how function approximation may be used to approximate this perfect control variate. Ehrlichman and Henderson [24] also developed a class of control variates for the American option pricing problem using multivariate adaptive regression splines.

These applications have shown the effectiveness of control variate techniques in various engineering and business problems. They also demonstrated the potential for the widespread use of control variate techniques.

COOPERATIVE GAME THEORY WITH NONTRANSFERABLE UTILITY

JUNGSUK OH
College of Business Administration,
Seoul National University,
Seoul, Korea

INTRODUCTION

The description and analysis of cooperative games become substantially simplified when one considers the case of transferable utility (TU), which is equivalent to the case of games with side payments. On the other hand, the situation in which a nontransferable utility (NTU) assumption is appropriate and detailed information regarding individual payoff configuration under various coalitional structure is available calls for an NTU modeling. Consider the following classic example by Roth [1].

Example 1 [1]. Consider a three-player game where each player acting alone yields payoff of zero for everyone, cooperation between Player 1 and 2 yields payoff configuration of $(1/2, 1/2, 0)$, cooperation between Player 1 and 3 yields $(p, 0, 1 - p)$, that between Player 2 and 3 yields $(0, p, 1 - p)$, and the grand coalition yields any convex combination of $(1/2, 1/2, 0)$, $(p, 0, 1 - p)$, and $(0, p, 1 - p)$. The coalitional form representation for this game under TU assumption would yield, along with the player set $N = \{1, 2, 3\}$, the following worth specifications:

$$\begin{aligned}v(i) &= 0 \quad i = 1, 2, 3 \\v(12) &= v(23) = v(13) = 1 \\v(N) &= 1.\end{aligned}$$

For the TU correspondence of this game, the core is empty and the Shapley (TU) value would be $(1/3, 1/3, 1/3)$. On the other

hand, it is apparent that an imposition of a NTU assumption for this game would make the TU solutions inappropriate due to the dependence of the payoff configuration on the parameter p , which is likely to yield an asymmetric payoff distribution if $p \neq 1/2$.

Consider an ordinary (TU) coalitional function $v(S)$ that assigns a real number (worth) to a coalition S . This single number of worth signifies the total payoff that members of S in aggregate can be entitled to. Furthermore, TU coalitional function form does not specify any mechanism of redistributing this sum among coalitional members. This means that the TU coalitional form game assumes that the worth of a coalition can be distributed without any restriction. These assumptions of ease of aggregation and redistribution of utilities for members of coalition have been subject to criticism. In particular, the following criticisms were raised by Aumann and Peleg [2]. First, the TU game construction assumes that there is a common medium of exchange through which members of a coalition can make side payments, which, in turn, transfer utility. Although money is a universal means of exchange in almost all economic contexts, use of it as means of aggregation and redistribution within a coalition may raise subtle issues or may not even be viable, depending on the context of the coalition formation.

Second, the TU game assumes that side payments are implementable both from the physical and legal perspectives. The physical means of side payments are usually assumed to be money so that, even in a global economy setting, a use of numeraire might do the job. However, in many industrial settings, side payments are subject to legal penalty, which limits the applicability of TU game instruments.

Third, it is assumed by the TU game that utility is unrestrictedly transferable, which, in turn, implies that each member's utility for medium of exchange is a linear function of the amount of medium. This assumption is equivalent to saying that the utility function

of a coalition member i is of a separable form

$$u_i(x_1, x_2, \dots, x_k) = v_i(x_1, x_2, \dots, x_{k-1}) + \delta_i x_k, \quad (1)$$

where good k represents the medium of exchange. With this setup, each member's utility function can be normalized by the factor δ_i , which makes it possible that transfers of the k th good entails a linear transfer of utility (i.e., the k th good serves as a medium of exchange). Considering this assumption of unrestricted utility transfer, the applicability of the TU game narrows down even further to those von Neumann–Morgenstern utility functions that are linear and increasing in the medium of exchange, that is, the quasi-linear utility function. Furthermore, as Varian [3] describes, even quasi-linear preferences allow for utility transfers only up to a certain range, which might further limit the applicability of TU games.

For these reasons, much efforts have been put forth to develop parallel cooperative game theories pertaining to contexts in which side payments are not possible, or, equivalently, utilities are nontransferable.

LINK TO NASH BARGAINING SOLUTION

Two axiomatic solution concepts of the cooperative game theory, the Shapley value [4] and the Nash bargaining solution (NBS) [5,6] have been the foundations for the development of the cooperative game theory. Unlike the Shapley value, which is a solution concept for a TU setting, the NBS is a solution applicable to an NTU game (and thereby, is also applicable to the TU game setting). Recognizing its nondependence on the TU assumption, the NBS quickly established itself as a status quo against which many subsequent works on approaches and results of solution concepts have been compared. Particularly, as the setting for the NBS is simple and elegant; there has been much contemplation and efforts on extending its settings, which shed further insights on the solution and, consequently, enrich the NTU cooperative game theory.

The static model of Nash contains a few elements. Let X be the feasible payoff space

and $u_i(x)$, ($i = 1, 2, x \in X$), the utility function for each player. (S, d) is the Nash bargaining problem where the feasible set $S = \{s_1, s_2\}$ is a convex, compact, and comprehensive set and $d = (d_1, d_2) \in S$ is the threat (or disagreement) point. Then, the classic NBS is a unique element in S that maximizes $(s_1 - d_1) \cdot (s_2 - d_2)$. Among various extensions of the two-person pure bargaining setting of Nash, a few are worth noticing. One obvious direction of extension is the development of the theory for the n -person setting, which is discussed in the subsequent subsection on values of NTU game.

Other extensions have taken place in directions that are based on contemplations on each element of Nash bargaining assumptions. Interpretation of cooperative game solutions as expected utility of playing a game was one such approach. After establishing the interpretation of the Shapley value for a TU game as a cardinal utility function [7,8], a similar attempt was made by Roth [9] in which the n -person bargaining problem with explicit consideration of players' risk attitudes was presented. Here, it was shown that the NBS is a solution corresponding to the risk neutral preference case. This treatment of the risk attitude can be viewed as a manipulation of the information contained in the feasible set S .

Binmore, Rubinstein and Wolinsky [10] provided an alternative way to extend the Nash bargaining problem via manipulation of the threat points d . Their framework was applied to two situations corresponding to different incentives to reach an agreement: players' impatience and fear of breakdown of the negotiation. They referred to the solution to their extended model time-preference Nash solution. Certainly, it is an appropriate description of the environment in which the bargaining takes place in an almost deterministic setting and, thus, losses associated with delays in reaching the agreement play a more important role than uncertainty. They also revealed that the limiting equilibrium outcome corresponds to the original NBS, that is, the positions corresponding to the maximum value of products of incremental gains of each player.

There are other extension works of the NBS. For example, Schmitz [11] considered a setting without the threat point. Thompson [12] and Thompson and Lensberg [13] incorporated the possibility that the set of players might change.

EFFECTIVITY CRITERIA AND COALITIONAL FORM NTU GAME

One of the important purposes that a coalitional form game serves is to predict prospects of various coalitions of a cooperative strategic-form game. Of course, given a strategic-form game, a specification of a coalitional function is a key task in identifying a coalitional form correspondence. As von Neumann and Morgenstern [14] suggested, maxmin criteria can be utilized to derive the coalitional function for a general nonzero sum game. Such an approach is evaluated to be “natural” in that the solution is both the maximum amount the player can guarantee for itself and the minimum amount to which the player can be driven by the opponent [15]. Sharing a similar spirit, two notions of “effectiveness” for the case without side payment were introduced in Aumann and Peleg [2] and Aumann [16]. These effectiveness concepts were products of an initial attempt to suggest ways to specify the worth of a coalition for the NTU strategic form game. Specifically, Aumann and Peleg [2] stated that

Intuitively, a coalition S is effective for a payoff vector x if the members of S , by joining forces, can play so that each player i in S receives at least x_i .

On the basis of this generalization of the maxmin approach of von Neumann and Morgenstern, the following definitions were proposed.

Definition 1. A coalition S is α -effective for a payoff vector x if there is a strategy for S such that for each strategy used by $N - S$, each member i of S receives at least x_i .

Definition 2. A coalition S is β -effective for a payoff vector x if for each strategy used by

$N - S$, there is a strategy for S such that each member i of S receives at least x_i .

An α -effective payoff is the amount that S can guarantee for its members regardless of actions of $N - S$, whereas a β -effective payoff is the amount that, through appropriate reaction to each action of $N - S$, S can guarantee for its members. Let $V_\alpha(S)$ and $V_\beta(S)$ be set of α -effective and β -effective payoffs for S respectively. Then, obviously, $V_\alpha(S) \subset V_\beta(S)$ for an NTU game. Moreover, for TU games, $V_\alpha(S) = V_\beta(S)$. The correspondence $V_\alpha(\cdot)$ and $V_\beta(\cdot)$ can be utilized to specify the coalitional form game of cooperative strategic-form game, and, hence, is referred to as α -effective and β -effective coalitional form of the strategic-form game. Although α -effectiveness possesses more intuitive appeal due to its invariant nature, β -effectiveness is more significant when used for the purpose of relating the coalitional function to the cooperative equilibria of a repeatedly played strategic-form game [16].

Example 2 [16]. Let $N = \{1, 2, 3\}$ and $S = \{1, 2\}$. Consider the following strategic form game.

Player		3
1,2	1, -1, arbitrary number	0,0, arbitrary number
	0,0, arbitrary number	-1, 1, arbitrary number

In reflection of the maxmin approach, one can ask the following question. What is the payoff guarantee, (x_1, x_2) , that S can make to its members? It is apparent for this example that, for a payoff vector of $(0, 0)$, S is β -effective but not α -effective.

Whichever way of specifying the coalitional function is utilized, the definition of an NTU coalitional form game is given via the coalitional function that assigns a feasible set for each coalition instead of a single number of worth as in TU coalitional form game.

Definition 3. An NTU game is denoted as (N, V) where N is the set of players and V is a coalitional function which assigns to each coalition $S \subset N$ the feasible payoff vectors of S , $V(S) \subset \mathbb{R}^S$. The feasible payoff vector, $V(S)$, is nonempty for $S \neq \emptyset$, closed, convex, and comprehensive (i.e., $x' \leq x \in V(S) \Rightarrow x' \in V(S)$).

In Definition 3, $V(N)$ is the set of all “feasible” or “attainable” payoff vectors. It is clearly visible from this definition of NTU game that a TU game is a special case of an NTU game. Each TU game (N, v) is equivalent to an NTU game (N, V_v) , where $V_v(S) = \{x \in \mathbb{R}^S : \sum_{i \in S} x_i \leq v(S)\}$ and $v(\cdot)$ is the worth function of (N, v) . Here, the game structure in which one can specify a single, real-number worth that bounds the sum of all members of a coalition enables the specification of a TU game.

Example 3 [Continued; [1]]. A coalitional form NTU game specification of the game in Example 1 would yield the following:

$$\begin{aligned} V(i) &= \{x \in \mathbb{R} : x_i \leq 0\} \quad i = 1, 2, 3 \\ V(1, 2) &= \{x \in \mathbb{R}^2 : (x_1, x_2) \leq (1/2, 1/2)\} \\ V(1, 3) &= \{x \in \mathbb{R}^2 : (x_1, x_3) \leq (p, 1-p)\} \\ V(2, 3) &= \{x \in \mathbb{R}^2 : (x_2, x_3) \leq (p, 1-p)\} \\ V(N) &= \left\{ \begin{array}{l} x \in \mathbb{R}^N : x \leq y \text{ for some } y \text{ in the} \\ \text{convex hull of} \\ (1/2, 1/2, 0), (p, 0, 1-p), \\ (0, p, 1-p) \end{array} \right\}. \end{aligned}$$

CORE OF THE NTU GAME

As one of the most natural solutions to the cooperative game, the core for the TU game, as explicitly defined by Gillies [17], quickly established itself as one of the main solution concepts of the cooperative game theory. One weakness of the core that this intuitive solution might not universally exist has prompted much research efforts to identify the conditions of its existence, which introduced important characterization concepts

and derivative solutions such as balancedness and the ε -core. Parallel efforts have been put forth on the core for the NTU games. First, Aumann [16] provided a mathematical framework for a parallel development of the theory of the core for the NTU game where formal definitions of a coalitional form NTU game and dominance, as well as suggestions for transforming a given normal form game into a coalitional form NTU game using α - and β -effectiveness concepts, which were originally proposed in Aumann and Peleg [2].

The following definition is useful in defining the core for an NTU game.

Definition 4. A coalition S can improve upon a payoff vector y if there is an $x \in V(S)$ such that $x_i > y_i$ for $\forall i \in S$.

Definition 5. The core $C(N, V)$ of an NTU game (N, V) is the set of payoff vectors in $V(N)$ that cannot be improved upon by any coalition. Formally

$$C(N, V) = V(N) \setminus \bigcup_{S \subset N} \text{int } V(S)$$

Example 4. Let $N = \{1, 2, 3\}$ and $0 \leq p < 1$. Let V be given by

$$\begin{aligned} V(i) &= \{x \in \mathbb{R} : x_i \leq p\} \quad i = 1, 2, 3 \\ V(i, j) &= \left\{ x \in \mathbb{R}^2 : x_i \leq 1, \text{ and } x_j \leq 1 \right\}, \text{ for } \forall i, \\ &\quad j \in N, i \neq j \\ V(N) &= \left\{ x \in \mathbb{R}^N : x_1 + x_2 + x_3 \leq 2 + p \right\}. \end{aligned}$$

Then, $C(N, V) = \{(1, 1, p), (1, p, 1), (p, 1, 1)\}$.

Scarf [18] developed an important generalization of the balanced game and nonemptiness condition for the core of an NTU game. Unlike the TU game counterpart in which nonemptiness and balancedness are both mutually necessary and sufficient, Scarf's theorem proves that balancedness is only a sufficient condition for nonemptiness of the core. Subsequent works on deriving necessary conditions for nonemptiness of the core including Billera [19] followed. Billera provided a refined concept of balancedness called π -balancedness, which is proved to be a necessary and sufficient condition of

nonemptiness of the core for hyperplane NTU games only. Recently, Predtetchinski and Herings [20] provided an extended criterion called π -balancedness, which is a necessary and sufficient condition for the core of an NTU game to be nonempty.

VALUES OF THE NTU GAME

Just as in the TU game context, various “solution” concepts applicable to NTU game context have been proposed and compared. For the two-person pure bargaining problem, NBS has long been established to be the central solution concept for the purpose of prediction of the outcome of the game. On the other hand, the axiomatic approach to the solution based on the notion of “fairness” resulted in the Shapley value. The class of solutions that belongs to the values of the NTU game shares the following characteristics, which allows one to perceive them as generalization of both the NBS as well as the Shapley value [21,22]. First, it is equivalent to the NBS when applied to the pure bargaining problem. Second, it is equivalent to the Shapley value when applied to the TU game. Third, the value component for an individual is proportional to the payoff of a player (scale covariance requirement).

Two NTU value concepts that share the above characteristics have been much discussed and compared: The Harsanyi NTU value [23,24] and the Shapley NTU value [25]. Both are generalizations of the NBS for the two-person pure bargaining problem to the n -person NTU game and, simultaneously, it generalizes the Shapley value for TU game to the NTU case. The Harsanyi NTU value arose as the first explicit solution concept as a value for the NTU game. The initial work of Harsanyi [23] had a shortcoming that it did not guarantee individual rationality, which was remedied in the subsequent work [24]. The Shapley NTU value is referred to as the λ -transfer value due to its construction process. Specifically, the NTU Shapley value identifies a TU game correspondence by allowing utility transfer at the rate λ . λ is referred to as the *weight vector* or *comparison vector*. Then, it uncovers the NTU value

for the original NTU game from the Shapley value for the derived TU game. Depending on the choice of the weight vector, the Shapley NTU value might not be unique [1].

In this section, the definition of the Shapley NTU value and a few numerical examples related to values of the NTU game are presented.

Definition 6. Given an NTU game (N, V) and a nonnegative weight vector $\lambda \in \mathbb{R}_+^N, \lambda \neq 0$, define a TU game (N, v_λ) by allowing transfers of utilities at the rates λ , that is, $v_\lambda(S) = \max \{ \sum_{i \in S} \lambda_i x_i : x \in V(S) \}$ for $\forall S \subset N$. A payoff vector x is the Shapley NTU value if $x \in V(N)$ and there exists a nonnegative vector $\lambda \in \mathbb{R}_+^N, \lambda \neq 0$ such that $\lambda_i x_i = \phi_i(N, v_\lambda)$, where $\phi_i(N, v_\lambda)$ is the TU Shapley value for (N, v_λ) .

The following two famous numerical examples are utilized in order to illustrate the construction processes of the Shapley NTU value.

Example 5 [22]. Consider the NTU game (N, V) with three players $N = \{1, 2, 3\}$ and its coalitional function specification is

$$\begin{aligned} V(i) &= \{x \in \mathbb{R} : x_i \leq 0\}, \quad i = 1, 2, 3, \\ V(1, 2) &= \{x \in \mathbb{R}^2 : x_1 + x_2 \leq 36, x_1 + 2x_2 \leq 36\}, \\ V(1, 3) &= \{x \in \mathbb{R}^2 : x_1 + x_3 \leq 0\}, \\ V(2, 3) &= \{x \in \mathbb{R}^2 : x_2 + x_3 \leq 0\}, \\ V(N) &= \{x \in \mathbb{R}^3 : x_1 + x_2 + x_3 \leq 36\}. \end{aligned}$$

Except for the coalitional function for $\{1, 2\}$, the (N, V) specification is similar to that of a TU game. For example, if one assigns a value of 36 as a worth of $\{1, 2\}$ instead of the above specification of $V(1, 2)$, (N, V) could conform to a TU game definition. In order to find the Shapley NTU value for (N, V) , one needs to first find the TU game correspondence via allowance of utility transfer at the rate λ . The TU game correspondence, (N, v_λ) , is obtained by specifying its worth: $v_\lambda(S) = \max \{ \sum_{i \in S} \lambda_i x_i : x_i \in V(S) \}$. In practice, Roth [1] suggested considering the

original NTU game with side payment for TU correspondence, which is equivalent to selecting the weight vector $\lambda = (1, 1, 1)$. Then, if the Shapley value for this TU game is feasible for the original game, it can also be viewed as the value for the original game in the spirit of Nash's axiom of independence of irrelevant alternatives.

For this game, (N, v_λ) with $\lambda = (1, 1, 1)$ is obtained by assigning worth v_λ for each coalition. Specifically,

$$v_\lambda(1, 2) = v_\lambda(1, 2, 3) = 36, \\ v_\lambda(i) = v_\lambda(1, 3) = v_\lambda(2, 3) = 0, \quad i = 1, 2, 3.$$

The Shapley TU value for (N, v_λ) can now be calculated to be $(18, 18, 0)$, which is also the Shapley NTU value since it is feasible for (N, V) .

The Shapley NTU value and the Harsanyi NTU value have been often compared against each other. The key difference lies in the order of placing emphasis upon equity and efficiency during the solution construction process. In the construction of the Shapley NTU value, it first determines the worth of the TU game correspondence for each subcoalition during which the efficiency of the subcoalition is emphasized. Then, it imposes the equity restriction by applying the Shapley TU value criteria. On the other hand, the Harsanyi NTU value utilizes the λ -egalitarian solution first, which restricts the specification of the potential of each subcoalition in comparison to the Shapley NTU value. McLean [27] summarized this difference as follows: "The Shapley NTU value emphasizes coalitional utilitarianism while the Harsanyi NTU value emphasizes coalitional equity."

Example 6 [Continued; [1]]. Suppose $p \in [0, 1/2]$ for the game in Example 1. Then, Roth [1] argues that $(1/2, 1/2, 0)$ is the only sensible solution if players are rational utility maximizers since $(1/2, 1/2, 0)$ is strictly preferred by $\{1, 2\}$ and Player 3 cannot contribute to them in achieving this payoff. On the other hand, the Harsanyi NTU value is $(\frac{1}{2} - \frac{p}{3}, \frac{1}{2} - \frac{p}{3}, \frac{2p}{3})$ and the Shapley NTU value is $(1/3, 1/3, 1/3)$ with $\lambda = (1, 1, 1)$ for both. Notice that the Shapley NTU value

coincides with that for the TU counterpart of the same game. The Shapley NTU value does not capture the asymmetric payoff configuration of this NTU game since its process of deriving the TU game correspondence by λ -transfer allowance yields a symmetric game. This feature of the Shapley NTU value is better highlighted by the axiomatization work of Hart [21]. Aumann [28] rebutted the claimed inadequacy of the Shapley NTU value in this example by arguing that there are circumstances in which the solution of $(1/3, 1/3, 1/3)$ might be justified. Specifically, there might be a suspicion between Player 1 and 2 in forming a coalition by themselves since a breakaway by either one of them and forming a coalition with Player 3 would leave that player with nothing. This argument is compelling if p is close to $1/2$, that is, one might roughly interpret p as the likelihood of coalition breakdown. Of course, this argument violates the spirit of group rationality since a coalition between Player 3 and either Player 1 or 2 yields weakly less payoff for Player 1 and 2. However, a fear of coalition breakdown might work in favor of Player 3 and it might be the ground for a positive share for Player 3. Notice that the Harsanyi NTU value captures the rebut rationale of Aumann in that, payoffs for Player 1 and 2 decrease, whereas that for Player 3 increases with higher p .

AXIOMATIZATION APPROACH

An axiomatic approach to a solution concept has a general merit that an axiomatic system for a solution consisting of intuitive and rationally acceptable sets of axioms can solidify its position as a natural solution. This has been the case for prevalent solution concepts such as the NBS, the core, and the Shapley value. Once its position establishes and its applications grow, examples that demonstrate counterintuitive results of the solution are, in many cases, viewed as anomalies instead of evidences that reject the validity and usefulness of the solution. The aforementioned argument between Roth [1] and Aumann [28] is one such example. Other examples of counterintuitive results include Shapley [29] in

which the core of a symmetric market game yields a result where sellers are entitled to all profit and Maschler [30] in which the bargaining set solution predicts better than the core in recognizing the benefit of cooperation in a market game. Although these and other examples are suggestive of ill-behaving potentials of these solutions, they have not threatened their central position in the theory of game.

In addition, axiomatization approach often shed important insights into solution concepts, particularly when axioms for various solutions are compared. Such benefits are highlighted in Peleg [31] in which an axiomatization of the core of NTU game was presented.

First, by obtaining axioms for the core, we single out important properties of solutions that determine the most stable solution in game theory. Second, we may compare the system of axioms for the core with systems of other solutions, and thereby obtain more information on solutions whose definition is not simple or 'natural'.

In other words, axiomatization of a game solution can identify essential and invariant values common to several solutions and, furthermore, can enhance the understanding of the nature of solutions whose definition is not intuitive. For these reasons, many solution concepts of the NTU game, due to their generally less apparent intuitive appeal compared to their TU counterparts, have been axiomatized. A representative of such efforts includes the following: Axiomatization of Core by Peleg [32], Shapley NTU value by Aumann [28], Harsanyi NTU value by Hart [21], Maschler–Owen NTU value by de Clippel *et al.* [33] and Hart [34,35]. More recently, Peleg and Sudholter [36] provided uniform and coherent axiomatizations for most of the main solutions of the cooperative games.

A few of the insights generated by these axiomatization endeavors might be worth mentioning. Close works between Aumann [28] and Hart [21] revealed that axioms that sufficiently define Shapley NTU value and Harsanyi NTU value are almost identical. Both are characterized by common axioms

such as efficiency, scale covariance, conditional additivity, independence of irrelevant alternatives, and unanimity. Hart [21] further identified the source of difference between Shapley NTU value and Harsanyi NTU value, which was attributed to the fact that, when determining the payoff for an intermediate coalition S , the Harsanyi solution takes into account subcoalitions of S , whereas the Shapley solution considers only the grand coalition. On the other hand, Peleg [32] provided the following axioms for the core: nonemptiness, individual rationality, the reduced game property (RGP), the converse reduced game property (CRGP). Such axiomatization of the core enabled a linkage between the core and other solutions such as the Nash bargaining and prekernel.

COOPERATIVE GAMES WITH TRANSFERABLE UTILITY

JENNIFER WILSON
The New School for Liberal
Arts, Eugene Lang College,
New York, New York

The theory of cooperative games was first introduced by von Neumann and Morgenstern who devoted the second half of their seminal book *Theory of Games and Economic Behavior* [1] to the theory of n -person games. As they noted, whenever a game has more than two players, the players' interests cannot be directly opposed. Thus, two or more players may find that they benefit by correlating their strategies. Since the underlying assumption behind noncooperative game theory is that players chose their actions without consultation, this leads to a new concept of a game in which players have the ability to communicate and make binding agreements. Under these assumptions, a number of new questions emerge, namely, which coalitions form and what role do these coalitions play in the players' strategies and in the outcome of the game. The following example illustrates these ideas.

Example 1 [Three-Person Game [2]]. Consider the zero-sum game presented in Table 1.

If the players have no opportunity to cooperate, they are likely to play according to their Nash equilibrium strategies (see *Nash Equilibrium (Pure and Mixed)*). There are two pure-strategy Nash equilibria in which players 1, 2, and 3 choose actions A, B , and A respectively or actions A, A , and B respectively. These yield the two outcomes $(-4, 1, 3)$ and $(-2, -1, 3)$. If two of the players can coordinate their strategies however, they will have a choice of four correlated strategies, each yielding different payoffs depending on the action of the remaining player. For instance, if players 2 and 3 form a coalition,

adding their payoffs together yields the two-person zero-sum game given in Table 2.

In this game, the principle of iterated dominance suggests that player 1 will choose A while the coalition of players 2 and 3 will choose action BA yielding payoffs of $(-4, 4)$. Similarly, if players 1 and 2 form a coalition, it results in another two-person zero-sum game against player 3 and has a unique minimax payoff using probabilistic strategies (see *Saddlepoints and von Neumann Minimax Theorem*), as does the game of players 1 and 3 against player 2. The payoffs of each of these games is given below, along with a breakdown of each coalition's utility among its members, assuming that members use their equilibrium strategies.

$$v(1) = -4 \quad v(23) = 4$$

utility for each player: $(-4, 1, 3)$

$$v(2) = -1.5 \quad v(13) = 1.5$$

utility for each player: $(-0.58, -1.5, 2.08)$

$$v(3) = -4.40 \quad v(12) = 4.40$$

utility for each player: $(-0.64, 5.04, -4.40)$

Based on the values that each coalition attains, it is clear that it is better to be a member of a coalition than to be left out. Players 1 and 2 would prefer to form a coalition with each other while player 3 would prefer to join player 2. However, if we examine each player's utility within the coalitions, we see that the situation is not that simple. Player 1 would do slightly better forming a coalition with player 3 who, knowing this, would prefer to form a coalition with player 1 over remaining alone. But what if player 2 could induce player 1 to stay with her by offering a *side payment* in which she transfers some of her utility to player 1? Player 3 might respond by making a counteroffer, which player 2 might offer to top. If a bidding war ensued, player 2 would win as she has enough utility to outbid player 3 while still making it advantageous for players 1

Table 1. Example 1: Three-Person Game

		Player 2					
		A			B		
Player 1	A	1	-2	1	-4	1	3
	B	3	1	-4	-5	10	-5

Player 3 = A

		Player 2					
		A			B		
Player 1	A	-2	-1	3	2	-4	2
	B	-6	12	-6	3	-1	-2

Player 3 = B

Table 2. Example 1: Player 1 versus Players 2 and 3

		Players 2 and 3							
		AA		AB		BA		BB	
Player 1	A	1	-1	-2	2	-4	4	2	-2
	B	3	-3	-6	6	-5	5	3	-3

and 2 to stay together rather than to defect individually to join player 3.

Considerations such as these led von Neumann and Morgenstern to consider coalitions and the values they can achieve as the fundamental objects on which to base a theory of cooperative games. The purpose of cooperative game theory as they conceived it, was to use the information embedded in the coalitional values to determine appropriate payoffs for each player, thereby defining the *solution* of a cooperative game. Since the publication of their book, cooperative game theory has focused primarily on defining and axiomatizing different solution concepts (see **The Shapley Value and Related Solution Concepts**). Other approaches to cooperative game theory include developing specific bargaining protocols and determining their equilibrium outcomes [3], and solving the general n -person bargaining problem.

Underlying the classical formation of cooperative game theory, are a number of assumptions. The first is that the players can communicate with one another and make binding agreements. The second is that they can make unlimited side payments to each other. As in the analysis of Example 1, this in effect allows them to redistribute the value of a coalition among the players in the coalition in any way they wish. Games in which this is allowed are called games with *transferable utility* or TU games. In TU games, it is reasonable to define the

value of a coalition in terms of a single number, with the understanding that the value corresponds to a whole set of possible payoffs among members of the coalition. Games in which players are not allowed to make side payments are called games with *nontransferable utility* or NTU games. In NTU games, the value of a coalition is defined explicitly as a set of allowable allocations to members of the coalition. In this article, we will focus on TU games. (NTU games are discussed in **Cooperative Game Theory with Nontransferable Utility**.) There are many excellent introductions to cooperative game theory including Refs 2, 4–8, as well as [1]. Our treatment adapts material from all of them. For additional resources, see the section titled “Extensions of Cooperative Game Theory” at the end of this article.

COOPERATIVE AND STRATEGIC FORM GAMES

A cooperative game is defined in terms of its *characteristic function* v which assigns a real number or value to each coalition of players in the game. We will assume throughout that the number of players is finite.

Definition 1. Let $N = \{1, 2, \dots, n\}$ be a set of players. A cooperative game is a function $v : 2^N \rightarrow \mathbb{R}$ such that $v(\emptyset) = 0$.

Note that when the number of players in a coalition is small, we will use notation such

as $v(i)$ to denote $v(\{i\})$ or $v(ij)$ to denote $v(\{i, j\})$, and so on.

From the example in the previous section, it is easy to see how a constant-sum strategic game can be converted into a cooperative game. For each coalition S , consider the two-person constant-sum game between S and $N \setminus S$. Assume that the utility of each coalition is equal to the sum of the utilities of the players in the coalition. Then let $v(S)$ be the value given to S when the two coalitions play their minimax strategies.

This definition of v captures the essence of the underlying constant-sum game since a coalition's interests are always in opposition to the interests of its complement. As the players in the complementary coalition $N \setminus S$ seek to maximize their own payoff, they automatically diminish the payoffs to S . Thus $v(S)$ represents the value that coalition S can reasonably expect for itself: a true "safety" value. Moreover, it is clear that the characteristic function will satisfy the following properties:

- constant-sum property: $v(S) + v(N \setminus S) = v(N)$ for all $S \subset N$,
- superadditivity: $v(S) + v(T) \leq v(S \cup T)$ for all $S, T \subset N$ such that $S \cap T = \emptyset$.

The first property stems from the definition of the value of a zero-sum game. The second property follows from the observation that if the players in S can guarantee themselves collectively at least $v(S)$ and the players in T can guarantee themselves at least $v(T)$, then by playing those strategies, the players in $S \cup T$ together can guarantee themselves at least $v(S) + v(T)$; by coordinating their strategies, they may in fact do better.

When the strategic game is not constant-sum, the relationship between the strategic game and its characteristic function is not as clear. The players' interests may not be directly opposed, and the highest utility of $N \setminus S$ may not correspond to the worst outcome for S . Nevertheless, von Neumann and Morgenstern suggested that the characteristic function for a non constant-sum game be derived in a manner analogous to that of a constant-sum game. Formally, this is achieved by the addition of a fictitious player

who has no strategic role but whose utilities are equal to the negative of the sum of the other players' utilities. This transforms the non constant-sum game into a zero-sum game. When the characteristic function is defined as above, each coalition S of original players is then given the value that the coalition receives by playing its minimax strategy in the zero-sum game based on the sum of the coalition members' utilities.

Example 2 [The Single Commodity Market [1]].

A seller (player 1) possesses an object that she values at c_1 . Players 2 and 3 are potential buyers who value the object at c_2 and c_3 respectively, where $0 \leq c_1 \leq c_2 \leq c_3$. Viewed as a strategic game, player 1 has the option of offering the object to player 2 or 3 and naming a price. The buyers have the option of suggesting their own price to player 1. The object changes hands only if player 1's offer to one of the buyers is equal to that buyer's offer; otherwise the object remains with player 1. Assume that the players' utilities, if no transaction takes place, are $(u_1, u_2, u_3) = (c_1, 0, 0)$, and if the object is sold to player i for price x , then $u_1 = x$, $u_i = c_i - x$ and the utility of the remaining player is unchanged.

What are the safety values of each coalition? Player 1 can guarantee herself at least c_1 (but no more) by offering an unacceptable price to the other two players. Players 2 and 3 are guaranteed no more than their current utility value of 0, either individually or together in a coalition. If players 1 and 2 form a coalition, they can guarantee themselves c_2 by agreeing on a price x and hence netting a total utility of $x + (c_2 - x) = c_2$. Similarly, the coalition of players 1 and 3 is guaranteed a value of c_3 , as is the coalition of all three players together. Hence, the characteristic function for this game is

$$\begin{aligned} v(1) &= c_1, & v(2) &= v(3) = v(23) = 0 \\ v(12) &= c_2, & v(13) &= v(123) = c_3. \end{aligned}$$

In this example, the characteristic function does not satisfy the constant-sum property but is still superadditive. In fact, any cooperative game whose characteristic function is derived from a strategic form game

in this manner will be superadditive by the previous argument.

The reverse implication is also true: any characteristic function v satisfying superadditivity can be interpreted as the characteristic function of a strategic game. Moreover if v is constant-sum, the corresponding strategic game will also be constant-sum [1]. To see this, suppose v is a superadditive cooperative game on a set of players N . We construct an explicit strategic game G having v as its characteristic function. Let the action of each player i in the game G be defined by picking a subset $S_i \subset N$ to which that player belongs. Once these are fixed, call a subset S a *ring* if $\{j : S_j = S\} = S$, meaning that each player in S chooses S as their subset. Consider the set of rings $\{\tilde{S}_1, \dots, \tilde{S}_m\}$. By definition, they are pairwise disjoint. Thus if $\tilde{S}_0$ is the set of players not in a ring, then $\{\tilde{S}_0, \tilde{S}_1, \dots, \tilde{S}_m\}$ forms a partition of N .

Now, let the utility functions for each player i in the game G be given by

$$u_i(S_1, \dots, S_n) = \begin{cases} \frac{1}{|\tilde{S}_k|} v(\tilde{S}_k) & \text{if } i \in \tilde{S}_k, k \neq 0, \\ v(i) & \text{if } i \in \tilde{S}_0. \end{cases}$$

This completes the definition of G . Let $\tilde{v}$ be the characteristic function of this game. We claim $\tilde{v} = v$. To see this, let S be a coalition and consider the value of $\tilde{v}(S)$. Now the members of S can guarantee that S will be a ring by each choosing S as their subset. If they do so, each member of S will receive $u_i = \frac{1}{|S|} v(S)$; collectively, they will receive $v(S)$. Thus the coalition S can guarantee itself $v(S)$, and hence $\tilde{v}(S) \geq v(S)$. Likewise, by a similar argument, the players in $N \setminus S$ can guarantee themselves $v(N \setminus S)$ by ensuring that $N \setminus S$ is a ring. Thus at worst, S must be a union of rings $S'_1, S'_2, \dots, S'_p$ and singletons S'_0 . It follows as before, that each $i \in S'_k$ receives $u_i = \frac{1}{|S'_k|} v(S'_k)$; together the members of S'_k receive $v(S'_k)$. Further, each $i \in S'_0$ receives $v(i)$; together they receive $\sum_{i \in S'_0} v(i)$. Since these sets are disjoint and v is superadditive, this implies $\tilde{v}(S) = \sum_{j=1}^p v(S'_j) + \sum_{i \in S'_0} v(i) \leq v(S)$. Hence, $\tilde{v}(S) = v(S)$. If in addition v is constant-sum, then so will be the strategic game.

The correspondence between strategic games and cooperative games is not one-to-one. Any characteristic function that is not superadditive cannot come from a strategic game, if the value of a coalition is defined as above by the coalition's safety value. Also, a characteristic function may correspond to many strategic games.

UTILITY THEORY AND MARKET GAMES

The ability to make side payments in cooperative TU game is often stated without specific reference to how or in what units the side payments are made. But in order for side payments to be meaningful: (i) there must be a single commodity (such as money) that can be transferred between players; (ii) the players must have an unlimited supply of it; and (iii) the players' rate of exchange of the commodity must be equal. Additionally, a player's utility function must reflect the outcome of the game as well as the money received or given. Aumann [9] proved that these assumptions imply that each player's utility u must be separable and increasing in money. This means that if P is the set of outcomes in the underlying strategic game, then u must be a function on $P \times \mathbb{R}$ of the form

$$u(p, \chi) = w(p) + c\chi,$$

where w depends only on p , $\chi \in \mathbb{R}$ represents the commodity being exchanged and $c \geq 0$. Now in general, a utility function can only be specified up to a positive linear transformation, so that if u represents the utility function of a player then so does $w = \alpha u + \beta$ for all real numbers $\alpha > 0$ and β . Thus, by possibly rescaling each player's utility function, we can assume that $c = 1$ for every player. Hence players can exchange money in a one-to-one way and the total amount of money in a game remains constant after side payments. If the value of $v(S)$ is expressed in units of money, its redistribution will reflect side payments as well as transfers of players' utilities.

These restrictions on players' utility functions are appropriate for many games including market and cost allocation games when all the players in the game have comparable

resources. But there are situations in which a player's utility is not linear in money. The utility of a wealthy individual may grow more slowly in money than a person with fewer resources. Additionally, there are many situations in life when side payments are either restricted or expressly forbidden, as when, for instance, anti-kickback laws are involved. In these cases, NTU game theory must be applied.

The relationship between utility and money in TU games is made explicit in the class of market games introduced by Shapley and Shubik [10].

Example 3 [Market Games]. A market for $N = \{1, 2, \dots, n\}$ traders and m commodities is defined by a quadruple $(N, \mathbb{R}_+^m, A, U)$ where $\mathbb{R}_+^m$ is the commodity space, $A = \{\mathbf{a}_i \in \mathbb{R}_+^m : i \in N\}$ is a set of initial allocations of the commodities among the traders, and $U = \{u_i : i \in N\}$ is a set of continuous and concave utility functions. Assume that u_i can be written as

$$u_i(\mathbf{x}, \chi) = w(\mathbf{x}) + c_i \chi,$$

where each w_i is continuous and concave on $\mathbf{x} \in \mathbb{R}_+^m$, $c_i \geq 0$, and $\chi \in \mathbb{R}$ is money. By possibly rescaling and translating the utility function (as described above), we can assume that $c_i = 1$ for all players i and that initially the players have no money.

Given a subset $\emptyset \neq S \subset N$, a *feasible S-allocation* is a set of allocations $\mathbf{x}_S = \{\mathbf{x}_i \in \mathbb{R}_+^m : i \in S\}$ such that $\sum_{i \in S} \mathbf{x}_i = \sum_{i \in S} \mathbf{a}_i$. Let X^S be the set of feasible S-allocations. (In practice, this allocation is accompanied by a sequence of side payments χ_i to player i such that $\sum_{i \in S} \chi_i = 0$. The total utility to members of S from such an allocation will then be $\sum_{i \in S} u_i(\mathbf{x}_i, \chi) = \sum_{i \in S} w_i(\mathbf{x}_i) + \sum_{i \in S} \chi_i = \sum_{i \in S} w_i(\mathbf{x}_i)$.)

Finally, for each S , let

$$v(S) = \max_{\mathbf{x} \in X^S} \left\{ \sum_{i \in S} w_i(\mathbf{x}_i) \right\}.$$

Example 4 [The Single Commodity Market Revisited]. The single commodity market with three players is a market game

with $m = 1$ and an initial allocation of $a_1 = 1$ and $a_2 = a_3 = 0$. The players' utilities are given by

$$u_i(x, \chi) = c_i x + \chi.$$

Consider the coalition $S = \{1, 2\}$, for example. Its feasible allocations will have the form $x_1 = x$ and $x_2 = 1 - x$ for some $0 \leq x \leq 1$. Since player 2 values the object more than player 1, the allocation resulting in maximum utility for the coalition S corresponds to $x = 0$. Hence $v(S) = c_1 \times 0 + c_2 \times 1 = c_2$. The other values of the characteristic function are derived in similar fashion.

Another of the best-known market games is the glove game [11].

Example 5 [Glove Game]. Let $N = N_1 \cup N_2$ be the union of two nonempty disjoint subsets. Suppose the number of commodities $m = 2$, and the initial allocations $A = \{\mathbf{a}_i \in \mathbb{R}_+^2 : i \in N\}$ are $\mathbf{a}_j = (1, 0)$ for each $j \in N_1$ and $\mathbf{a}_k = (0, 1)$ for each $k \in N_2$. Let the utility function w_i for player i be given by $w_i = \min\{x_1, x_2\}$ where (x_1, x_2) is any initial or subsequent allocation. Then $(N, \mathbb{R}_+^2, A, U)$ is a market and it is easily seen that

$$v(S) = \min\{|S \cap N_1|, |S \cap N_2|\}$$

for all $S \subset N$. This game is called the *glove game* for its analogy to a market for pairs of gloves in which initially some players have a left-handed glove, the remainder have a right-handed glove, and the value of any coalition S is equal to the total number of pairs of gloves $v(S)$ among its members.

PROPERTIES OF COOPERATIVE GAMES

As noted in the section titled "Cooperative and Strategic Form Games," cooperative games that are derived from strategic form games will be superadditive. But there are games of interest that are not superadditive—in particular those modeling situations where antitrust laws prevent players from creating coalitions that are too large. In such cases, the characteristic function will reflect the fact that is not always advantageous to form coalitions.

We will assume, unless otherwise stated, that v is superadditive. Note that in this case, $\sum_{i \in N} v(i) \leq v(N)$. If $\sum_{i \in N} v(i) = v(N)$, then the game is additive: players gain nothing by forming coalitions, and hence should be allocated the value $v(i)$.

Definition 2. A cooperative game v is called *inessential* if $\sum_{i \in N} v(i) = v(N)$. A cooperative game v is *essential* if $\sum_{i \in N} v(i) < v(N)$.

Definition 3. A cooperative game v is *monotonic* if $v(S) \leq v(T)$ for every $S \subset T$.

Many solution concepts in cooperative game theory are built around a player's *marginal contribution* to a coalition S . If $i \notin S$, this is given by $v(S \cup i) - v(S)$. If v is monotonic, a player's marginal contributions will always be nonnegative.

Definition 4. A cooperative game v is *convex* if $v(S) + v(T) \leq v(S \cup T) + v(S \cap T)$ for all $S, T \subset N$.

Convexity is equivalent to the following statement [6]:

$$\begin{aligned} \text{If } S \subsetneq T \text{ and } i \notin T, \text{ then} \\ v(S \cup i) - v(S) \leq v(T \cup i) - v(T). \end{aligned}$$

In other words, the larger the coalition, the larger the marginal contribution of potential members to the coalition.

It is clear that convexity implies superadditivity. Superadditivity however does not imply convexity.

Example 6. Let v be the cooperative game on three players given by

$$\begin{aligned} v(1) = 1 \quad v(2) = v(3) = v(23) = 0 \\ v(12) = 4 \quad v(13) = 2 \quad v(123) = 4. \end{aligned}$$

Then v is an essential superadditive game but v is not convex since $v(12) + v(13) > v(123) + v(1)$.

Superadditivity also does not imply monotonicity unless v is *positive* (its range

restricted to nonnegative numbers); nor does monotonicity imply either superadditivity or convexity. The following two examples demonstrate why these implications fail.

Example 7. Let v be the cooperative game on two players given by

$$v(1) = -2 \quad v(2) = 1 \quad v(12) = 0.$$

Then v is an essential superadditive game but v is not monotonic since $v(2) > v(12)$.

Example 8. Let v be the cooperative game on three players given by

$$\begin{aligned} v(1) = v(2) = v(3) = 2 \\ v(12) = v(13) = v(23) = 3 \quad v(123) = 4. \end{aligned}$$

Then v is a monotonic game but v is not superadditive since $v(1) + v(23) > v(123)$.

Definition 5. A cooperative game v is *symmetric* if $v(S)$ depends only on the size $|S|$ of S for all $S \subset N$.

Definition 6. A cooperative game is *simple* if it is monotonic and if $v(S) = 0$ or 1 for all $S \subset N$.

One of the most useful concepts for classifying cooperative games is that of strategic equivalence. Strategic equivalence arises because, as with strategic games, cooperative games may have different definitions yet yield the same strategic considerations.

Definition 7. Let N be a set of players. Two cooperative games v and w on N are called *strategically equivalent* if there exist constants $a > 0$ and $\{b_i : i \in N\}$ such that for all $S \subset N$,

$$w(S) = av(S) + \sum_{i \in S} b_i.$$

Suppose v is a (superadditive) cooperative game corresponding to a strategic game G . Since the utility functions of the players in G are defined only up to positive linear transformation, a reasonable question to ask is how

v is affected by a change in those utility functions. Since side payments are permitted, the only transformations of the utility functions allowed are those of the form

$$\tilde{u}_i(p, \chi) = a[u_i(p, \chi)] + b_i = aw(p) + a\chi + b_i$$

for all outcomes p and money χ , where $a > 0$ is the same for all players i . We can interpret this transformation by saying each player receives an additional b_i and that the unit of exchange has been scaled up by a factor of a . Summing these over a coalition S yields a new characteristic function $\tilde{v}$ such that

$$\begin{aligned} \tilde{v}(S) &= \sum_{i \in S} \tilde{u}_i(\mathbf{x}, \chi) = a \sum_{i \in S} u_i(\mathbf{x}, \chi) \\ &\quad + \sum_{i \in S} b_i = av(S) + \sum_{i \in S} b_i. \end{aligned}$$

Thus, the new cooperative game $\tilde{v}$ is strategically equivalent to v .

Strategic equivalence defines an equivalence relationship on cooperative games. Two members of each equivalence class of particular note are the *(0)-normalization* and the *(0,1)-normalization* of a characteristic function v . The *(0)-normalization*, given by $w_1(S) = v(S) - \sum_{i \in S} v(i)$, satisfies $w_1(i) = 0$ for each i . The *(0,1)-normalization*, given by $w_2(S) = \frac{v(S) - \sum_{i \in S} v(i)}{v(N) - \sum_{i \in N} v(i)}$, also satisfies $w_2(N) = 1$. Both convexity and superadditivity are preserved under strategic equivalence, however monotonicity or lack of monotonicity is not [6]. In fact the *(0,1)-normalization* of the game in Example 7 is the monotonic game $v(1) = v(2) = 0$ and $v(12) = 1$. A more useful property that is preserved under strategic equivalence is *zero-monotonicity*. A cooperative game v is zero-monotonic if its *(0,1)-normalization* is monotonic.

The set of cooperative games on a player set N is endowed with the usual addition and scalar multiplication of the characteristic functions, and hence forms a vector space. It has a basis given by the set of unanimity games v_T , defined as follows:

Definition 8. Given a subset $\emptyset \subset T \subset N$, the unanimity game v_T is given by

$$v_T(S) = \begin{cases} 1, & \text{if } T \subset S, \\ 0, & \text{else.} \end{cases}$$

In fact, each cooperative game v can be written as $v = \sum_{T \subset N} c_T v_T$, where $c_T = \sum_{\{T' : T' \subset T\}} (-1)^{|T|-|T'|} v(T')$ [4].

Finally, there are several oft-used methods to combine cooperative games into new games.

Definition 9. The *dual* of a cooperative game v is the cooperative game v' , where $v'(S) = v(N) - v(N \setminus S)$ for all $S \subset N$.

If $v(S)$ represents the value that S can guarantee itself, $v'(S)$ represents the portion of the total value of the game $v(N)$ that cannot be claimed by $N \setminus S$. Clearly, a game is self-dual if and only if it is constant-sum.

Definition 10. Let $N' \subset N$ be a subset of players. The *subgame* v' corresponding to N' is given by $v'(S') = v(S')$ for all $S' \subset N'$.

Definition 11. Let $N_1, N_2, \dots, N_m$ be disjoint sets of players, and let $w_1, w_2, \dots, w_m$ be simple games with player sets $N_1, N_2, \dots, N_m$ respectively. Let v be a positive game on the player set $N_0 = \{1, 2, \dots, m\}$. Then the *composition* of v with the w_i is the cooperative game u on the player set $N = N_1 \cup N_2 \cup \dots \cup N_m$ given by

$$u(S) = v(\{j : w_j(S \cap N_j) = 1\})$$

for all $S \subset N$. The composition is denoted by $u = v[w_1, \dots, w_n]$.

COST GAMES

A cost game is one where the players have some common goal (such as gaining access to a public service or building infrastructure) and may obtain some benefit from sharing costs. Given a set of players N and a subset $S \subset N$, let $c(S)$ denote the costs associated with all the members of S receiving the public benefit. Then the associated cost-savings game is given by the characteristic function v where

$$v(S) = \sum_{i \in S} c(i) - c(S).$$

Table 3. Cost and Cost-Savings Functions for Examples 9 and 10

Subsets (S)	Tennessee Valley Authority		Minimum Cost Spanning Tree	
	Cost [$c(S)$]	Savings [$v(S)$]	Cost [$c(S)$]	Savings [$v(S)$]
$\emptyset$	0	0	0	0
A	163,520	0	20	0
B	140,826	0	40	0
C	250,096	0	30	0
AB	301,607	2,739	40	20
AC	378,821	34,795	40	10
BC	367,370	23,552	40	30
ABC	412,584	141,858	50	40

The function v represents the *savings* each coalition gains through collaborating on costs.

Example 9 [Tennessee Valley Authority [12]]. In the 1930s, the Tennessee Valley Authority proposed a project to build a series of dams and reservoirs along the Tennessee River to improve navigation, control flooding, and generate hydroelectric power. Because the costs involved in attaining the project's goals were interdependent, estimations were made for the costs of each possible combination of goals. Let A, B, and C stand for the goals of improved navigation, flood control, and hydroelectric power respectively; these act as the players in a cost allocation game. The associated cost and cost-savings functions are listed in the first three columns of Table 3.

In any cost-savings game, $v(i) = 0$ for all individual players i . The characteristic function v will be superadditive if and only if c is *subadditive* ($c(S) + c(T) \geq c(S \cup T)$ for all disjoint S and T). It will also be convex if and only if c is *concave* ($c(S) + c(T) \geq c(S \cup T) + c(S \cap T)$) [8].

Example 10 [Minimum Cost Spanning Tree [8]]. Three towns A, B, and C wish to receive electrical power from a power company O. The costs of connecting each town to the power company are given by 20, 40, and 30 respectively. Also, the cost of connecting A to B is 20, connecting A to C is 20, and connecting B to C is 10. These facts can be modeled by a graph with vertices A, B, C, and

O and edges weighted with the cost between corresponding vertices. The cost function of a coalition is found by determining the minimal cost tree spanning O and the towns in the coalition. Towns 2 and 3, for instance, can be connected in a number of ways, the cheapest of which uses the edges OC and CB for a cost of $30 + 10 = 40$. The cost and cost-savings functions are listed in the last two columns of Table 3.

For more on cost allocation games, see **Power Indices**. A good survey of cost allocation can be found in Ref. 13 and an analysis of minimum cost spanning trees can be found in Ref. 14.

SIMPLE GAMES

Simple games are most often used to model voting situations in which the object of the game is to approve a bill or decision. Coalitions S such that $v(S) = 1$ are called *winning* coalitions; the remainder are *losing* coalitions. For a simple game not to be superadditive, there must be two disjoint coalitions S and T such that $v(S) + v(T) > v(S \cup T)$. This can only happen if $v(S) = v(T) = 1$. A game such as this is called *improper* and is clearly undesirable from a legislative point of view since two separate coalitions could pass conflicting resolutions. Simple games for which this does not happen are called *proper*. A simple game is proper if and only if it is superadditive.

A simple game is *strong* if for every coalition S , either S or $N \setminus S$ is winning. A simple game that is both proper and strong is

constant-sum and hence self-dual. Such a game is called *decisive*.

The marginal contributions of a player in a simple game can take on only the values 0 or 1. A player $i \notin S$ such that $v(S \cup i) - v(S) = 1$ is called *critical* for that coalition since inclusion of the player is required for the coalition to be winning. A player i that is critical for no coalition S is called a *dummy*; a player i that is critical for all coalitions S is called a *dictator*. A coalition S for which each member is critical is called a *minimal winning coalition*. Since simple games are monotonic, the set of minimal winning coalitions completely defines a simple game.

The dual of a simple game is also a simple game. The winning coalitions of v' are exactly the losing coalitions of v . Hence v' may be interpreted as the associated “blocking game.”

There are a number of well-known families of simple games. The n -person *unanimity game* is the simple v game such that $v(S) = 0$ except when $S = N$. The n -person *majority game* is the symmetric game v such that $v(S) = 1$ if and only if $|S| \geq \lfloor n/2 \rfloor + 1$.

A simple game is a weighted voting game if each of the players can be assigned a nonnegative weight such that the winning coalitions are precisely those coalitions in which the total weight of the players in the coalition is equal to or greater than some predetermined quota. A majority game is a weighted voting game in which each player is given a weight of one and the quota is equal to $\lfloor n/2 \rfloor + 1$. Weighted voting games in which the quota is more than half the total weight of all the players will always be proper (although not necessarily strong).

Example 11 [United Nations Security Council]. The United Nations Security Council is made up of 5 permanent members and 10 rotating members. A coalition is winning if and only if it contains all the permanent members and has at least 9 members in total. This scenario can be represented by a weighted voting game in which the weight of each permanent member is 7, the weight of each rotating member is 1 and the quota is 39.

Simple games can be combined in several ways. Suppose v and w are simple games on the same player set N . Then $v \otimes w$ and $v \oplus w$ are the simple games on N given by

$$v \otimes w(S) = \begin{cases} 1, & \text{if } v(S) = 1 \text{ and } w(S) = 1; \\ 0, & \text{else;} \end{cases}$$

$$v \oplus w(S) = \begin{cases} 1, & \text{if } v(S) = 1 \text{ or } w(S) = 1; \\ 0, & \text{else.} \end{cases}$$

Coalitions in $v \otimes w$ are winning if and only if they are winning in both v and w ; coalitions in $v \oplus w$ are winning if and only if they are winning in at least one of v and w . It is clear from the formulation that

$$v \otimes w = u_1[v, w] \quad \text{and} \quad v \oplus w = u_2[v, w],$$

where u_1 and u_2 are the two-player games $u_1(S) = 1$ if and only if $S = N$, and $u_2(S) = 1$ if and only if $S \neq \emptyset$ respectively. These definitions can be extended in the obvious way to $v_1 \otimes v_2 \otimes \cdots \otimes v_m$ and $v_1 \oplus v_2 \oplus \cdots \oplus v_m$.

For more about simple games, see **Power Indices**. Good introductions to simple games can be found in Refs 15 and 16.

SOLUTION CONCEPTS FOR COOPERATIVE GAMES

The primary objective in traditional cooperative game theory is to determine an appropriate allocation or set of allocations of utility among a game's players based on the characteristic function. Assuming that the game is superadditive and essential, two reasonable restrictions immediately present themselves. The first is that each player receives in the allocation at least as much as the player could receive on his/her own. This is called the *principle of individual rationality*. The second is that the sum of the allocations be equal to the value of the grand coalition. This is called *efficiency* or the *principle of group rationality*. It is also an application of the Pareto principle that if an allocation among the players adds up to less than $v(N)$, it is desirable to look for an increase in allocation that does not harm any player and is strictly better for at least one player. von Neumann and

Morgenstern called any allocation meeting these requirements an *imputation* [1].

Definition 12. The vector $\mathbf{x} \in \mathbb{R}^n$ is an *imputation* if it satisfies $x_i \geq v(i)$ and $\sum_i x_i = v(N)$.

Most solution concepts focus on the set of imputations and attempt to restrict the set to a single imputation or subset of imputations based on the perceived “stability” of the allocation to threats from coalitions wanting to break away, or on some externally determined principles of fairness.

The simplest solution concept is the *core* $C(v) = \{\mathbf{x} \in \mathbb{R}^n \mid \sum_{i \in S} x_i \geq v(S) \text{ for all } S \subset N\}$. An imputation will be in the core if no coalition has an incentive to break away from the grand coalition.

A closely related concept is that of *dominance*.

Definition 13. An imputation $\mathbf{y}$ is said to *dominate* an imputation $\mathbf{x}$ if there is some coalition S such that $y_i > x_i$ for all $i \in S$ and $\sum_{i \in S} y_i \leq v(S)$.

Informally, $\mathbf{y}$ dominates $\mathbf{x}$ if it is better for all members of S and it is feasible; that is, the values of y_i for all i in S sum to at most $v(S)$. The *dominance core* $DC(v)$ is the set of undominated imputations.

Note that if $\mathbf{x}$ is dominated by $\mathbf{y}$ via the coalition S , then $\sum_{i \in S} x_i < \sum_{i \in S} y_i \leq v(S)$. Hence, $\mathbf{x}$ is not in the core. Alternatively, if $\mathbf{x}$ is not in the core then it is possible to find an imputation $\mathbf{y}$ that dominates $\mathbf{x}$. Suppose $\sum_{i \in S} x_i < v(S)$ for some coalition S . Define $\mathbf{y} \in \mathbb{R}^n$ by

$$y_i = \begin{cases} x_i + \frac{1}{S}[v(S) - \sum_{i \in S} x_i], & \text{if } i \in S; \\ v(i) + \frac{1}{N \setminus S}[v(N) - v(S) - \sum_{i \in N \setminus S} v(i)], & \text{if } i \notin S. \end{cases}$$

It is easy to see that $\mathbf{y}$ dominates $\mathbf{x}$ on S and that $\mathbf{y}$ is an imputation (if v is superadditive). Hence $C(v) = DC(v)$ for all superadditive v .

Example 12 [The Single Commodity Market Revisited]. In this example, an imputation is any (x_1, x_2, x_3) such that

$$\begin{aligned} x_1 &\geq c_1, \quad x_2 \geq 0, \quad x_3 \geq 0, \quad \text{and} \\ x_1 + x_2 + x_3 &= c_3. \end{aligned}$$

An imputation is in the core if it additionally satisfies

$$\begin{aligned} x_1 + x_2 &\geq c_2, \quad x_1 + x_3 \geq c_3, \quad \text{and} \\ x_2 + x_3 &\geq 0. \end{aligned}$$

Hence, the core consists of all allocations of the form $(x, 0, c_3 - x)$ where $c_2 \leq x \leq c_3$.

Unfortunately, the core of some games is empty.

Example 13 [Majority Rule]. Let v be the majority game on three players. So

$$\begin{aligned} v(1) &= v(2) = v(3) = 0, \\ v(12) &= v(13) = v(23) = v(123) = 1. \end{aligned}$$

For $\mathbf{x}$ to be in the core, it must satisfy

$$\begin{aligned} x_i &\geq 0, \quad x_i + x_j \geq 1, \\ \text{and} \quad x_1 + x_2 + x_3 &= 1. \end{aligned}$$

Clearly, there is no solution to this problem.

As in the example above, many cooperative games have empty cores, and hence no imputations that are undominated. von Neumann and Morgenstern [1] proposed the concept of a stable set as a solution. A set of imputations is stable if no imputation in the stable set dominates another in the set, and if every imputation outside the stable set is dominated by an imputation inside the stable set. For more on cores and stable sets. Other solutions attempt to minimize the incentive for a coalition or individual to break away from the proposed allocation(s). These include the nucleolus, the kernel, and the related bargaining set.

The best-known solution concept for cooperative games is the Shapley value [17]. The Shapley value gives to each player a weighted average of the player’s marginal contributions to each coalition; that is, a sum of terms of the form $v(S \cup i) - v(S)$. One of

the strengths of the Shapley value is that it is the unique solution concept satisfying several intuitive “fairness” criteria. It also arises as the solution to a two-person bargaining problem, and is open to a number of other useful interpretations. Applied to simple games, it is one common measure of a player’s *power* in a voting situation (see **The Shapley Value and Related Solution Concepts** and **Power Indices**).

ALTERNATIVES TO THE CHARACTERISTIC FUNCTION

One of the drawbacks to using the characteristic function to describe cooperation between players in a strategic game is that it fails to make visible the details of the players’ strategies in the original game. The following well-known example is often used to illustrate the limitations of the characteristic function in fully describing the dynamics of the players’ interactions, in particular the use of threats as bargaining positions.

Example 14 [Employer–Worker [7]]. A worker can threaten to stop working for her employer, thereby preventing the employer from benefiting from her labors. Assume the actions and payoffs of the players are as described in Table 4.

Viewed as a strategic game, it is clear that the worker’s ability to threaten the employer is limited by the severity of the penalty against herself if she does so. Indeed the Nash equilibrium of this game is for the worker to retract and the employer to resist, yielding a payoff of (0, 10).

The characteristic function of the associated cooperative game is

$$v(W) = 0, \quad v(E) = 5, \quad \text{and} \quad v(WE) = 10.$$

Table 4. Example 14: Worker versus Employer

		Employer			
		Resist		Accede	
Worker	Insist	−1000	0	5	5
	Retract	0	10	0	10

In this formulation, the worker is disadvantaged, but the much stronger position of the employer is not obvious.

Shubik [7] called strategic games that translate well into cooperative game *c-games*. Constant-sum games, in which a coalition’s interests are directly opposed to that of the coalition’s complement are *c-games*. But many non constant-sum games are not. In Example 14, for instance, it is not in the best interests of the worker to insist, hence the employer’s equilibrium payoff in the strategic game is higher than the value of $v(E)$ which is based on the assumption that the worker will choose her strategy so as to minimize her employer’s payoff. But the worker is unlikely to act in this way because she can do better by retracting. Similarly, for general non constant-sum games, it may often be in the best interests of the players to cooperate. Among non constant-sum games that are represented well by their characteristic function, Shubik identified the games of consent or games of orthogonal coalitions. In these games, players’ payoffs are determined only by the coalitions they belong to; the strategies of the complementary coalition do not affect their value. Several classes of market games fall into this category [10,11].

For other types of non constant-sum games, Shubik suggested adapting a concept from the bargaining literature to define a new characteristic function called the *extended characteristic function* h . Bargaining theory has a well-developed history beginning in 1950 when Nash introduced the two-person bargaining problem for TU games and proposed a unique solution now called the *Nash bargaining solution* [18]. The solution was later extended to NTU games by Selten [19]. Harsanyi [20] remarked that these ideas could be adapted to determine the value of a coalition in cooperative game theory by supposing the coalitions S and $N \setminus S$ to be engaged in a two-person bargaining game.

This idea uses the fact that a two-person non constant-sum game in strategic form G can be written as the sum

$$G = \frac{1}{2}[G^+ + G^-]$$

where G^+ is the symmetric game in which the players receive identical payoffs equal to the sum of the original individual payoffs and G^- is the zero-sum game in which the players receive the difference of their individual payoffs. The bargaining solution to this problem is for the players to receive the amounts

$$h(1) = \frac{1}{2} [\text{val}G^+ + \text{val}G^-] \quad \text{and} \\ h(2) = \frac{1}{2} [\text{val}G^+ - \text{val}G^-]$$

respectively, where $\text{val}G^+$ is the maximum utility that the players can receive in the game G^+ and $\text{val}G^-$ is the value of the game G^- when the players play their minimax strategies. We illustrate with Example 15.

Example 15 [Employer–Worker Revisited [7]]. The composite games G^+ and G^- are given in Table 5.

Game G^+ has a maximum value of 10 and G^- has a saddlepoint of -10 . This gives $h(W) = 0$ and $h(E) = 10$, which more closely mirrors the weakness of the worker’s position.

We illustrate another use of the extended characteristic function in the bankruptcy game [21]. As discussed by O’Neil, an early version of the bankruptcy game can be found in a passage in the Babylonian Talmud in which Rabbi Abraham Ibn Ezra illustrates how Jewish laws of inheritance can be applied to divide the estate of the biblical figure of Jacob. According to Rabbi Ibn Ezra, after his father’s death, Jacob’s eldest son Reuben produced a deed stating that Jacob had left his entire estate to him. His second son Simeon produced a similar deed stating that Jacob had left half his estate to him. Similarly his sons Levi and Judah claimed one-third and one-fourth of the estate respectively. Using the principles

described by Rabbi Ibn Ezra, this problem can be modeled as follows.

Example 16 [The Bankruptcy Game [21]]. A man dies leaving an estate valued at 120. His sons, (numbered 1, 2, 3, and 4), claim portions valued at 120, 60, 40, and 30 respectively. Assume that the estate is infinitely divisible, that each son must claim a specific section of the estate, and that any portion of the estate that is claimed by more than one son is divided evenly between the claimants.

To determine the value of the extended characteristic function for a coalition, say, $S = \{1, 3\}$, note that together Rueben and Levi can claim the entire estate worth 120. The complementary sons, Simeon and Judah, will claim nonoverlapping pieces totaling $60 + 30 = 90$. Thus the claim of Simeon and Judah will inevitably overlap with that of Levi (and Rueben). Assume the overlap with Levi has length x . Then three sons lay claim to a portion of the estate of length x , two sons lay claim to a portion of length $90 - x$, and Reuben has the only claim to a portion of length 30. Thus, Reuben and Levi will get $(2/3)x + (1/2)(90 - x) + 30 = 75 + (1/6)x$ and Simeon and Judah will get $(1/3)x + (1/2)(90 - x) = 45 - (1/6)x$, resulting in a difference of $30 + (1/3)x$. Reuben and Levi will seek to maximize x while Simeon and Judah will seek to minimize x . The coalitions’ optimal strategies, therefore, are to chose their claims randomly, resulting in an expected overlap of $x = (90 \cdot 40)/120 = 30$ and an expected difference of $30 + (1/3)30 = 40$. Thus $h(13) = (1/2)[120 + 40] = 80$ and $h(24) = (1/2)[120 - 40] = 40$. The other values can be computed similarly.

The values obtained by the extended characteristic function can be contrasted with those of v . The value $v(13)$ is based

Table 5. Example 15: Worker versus Employer Revisited

		Employer	
		Resist	Accede
Worker	Insist	−1000	10
	Retract	10	10

Symmetric Game G^+

		Employer	
		Resist	Accede
Worker	Insist	−1000	0
	Retract	−10	−10

Zero-Sum Game G^-

on the assumption that Simon and Judah act to minimize Reuben and Levi's claim. This means that they will choose their claims so that the overlap x is 0, yielding a value of $v(13) = 75 + (1/6)0 = 75$. Alternatively, if Reuben and Levi act to minimize Simon and Judah claim, they will ensure that the overlap x is 40 leading to $v(24) = 45 - (1/6)40 = 105/3$.

It can easily be seen that $h \geq v$ for all strategic games, and that when the strategic game is constant-sum, the two functions are equal [6].

NONTRANSFERABLE UTILITY COOPERATIVE GAMES

The theory of nontransferable cooperative games was introduced by Aumann and Peleg [22] to model situations when the assumptions of TU do not hold. In these circumstances, the allocations accessible to members of a coalition cannot be expressed as a single number but as a set of payoffs to each coalition member that summarize all the possible allocations available to the coalition. There are two standard ways of defining these sets, each using different underlying concepts of a coalition's "safety" value(s), usually referred to as *alpha* theory and *beta* theory. To distinguish between these two definitions of $v(S)$, we use the notation v for alpha theory and $\tilde{v}$ for beta theory.

In alpha theory, $v(S)$ is defined as the set of payoffs that the players can guarantee themselves regardless of what strategies are used by the players in $N \setminus S$. In other words, a payoff $(x_1, x_2, \dots, x_n) \in \mathbb{R}^n$ is in $v(S)$ if the members of S have a set of strategies $(\delta_j)_{j \in S}$ such that for all possible strategies $(\delta_k)_{k \in N \setminus S}$ of $N \setminus S$, $u_i((\delta_j)_{j \in S}, (\delta_k)_{k \in N \setminus S}) \geq x_i$ for each player $i \in S$ where u_i is the utility function of player i .

Alternatively, in beta theory, $\tilde{v}(S)$ is defined as the set of payoffs that the opposing coalition cannot prevent. That is, a payoff $(x_1, x_2, \dots, x_n) \in \mathbb{R}^n$ is in $\tilde{v}(S)$ if for every possible set of strategies $(\delta_k)_{k \in N \setminus S}$ of $N \setminus S$ there is a set of strategies $(\delta_j)_{j \in S}$ of S such

that $u_i((\delta_j)_{j \in S}, (\delta_k)_{k \in N \setminus S}) \geq x_i$ for each player $i \in S$.

Since the requirements for alpha theory are stronger than those for beta theory, $v(S) \subset \tilde{v}(S)$. If the game is TU (and is finite), the two notions coincide. However, for general NTU games, this will not be the case [4].

Assume that the set of strategies is compact and the utility functions of the players are continuous and concave. Then, regardless of which definition is used, the characteristic function (now simply denoted v) will satisfy the following properties [8]:

- For each $\emptyset \neq S \subset N$, $v(S)$ is a nonempty closed convex subset of $\mathbb{R}^n$.
- If $\mathbf{x} \in v(S)$ and $y_i \leq x_i$ for all $i \in S$, then $\mathbf{y} \in v(S)$.
- If $S \cap T = \emptyset$, then $v(S) \cap v(T) \subset v(S \cup T)$.
- For each $S \subset N$, there exists $\mathbf{y} \in \mathbb{R}^n$ such that $\mathbf{x}_i \leq y_i$ for all $\mathbf{x}_i \in S$.

The second condition is referred to as comprehensiveness and states that if the members of S can obtain a set of payoffs $\mathbf{x}$, then they can also obtain less. The last condition guarantees that $v(N)$ is not too big. These properties are used to motivate the following definition.

Definition 14. A cooperative game with non-transferable utility is a triple (N, v, H) where N is a finite player set, H is a convex, compact polyhedral subset of $\mathbb{R}^n$, and v is a function that assigns to each subset $S \subset N$ a subset $v(S) \in \mathbb{R}^n$ satisfying the following conditions:

- for each $\emptyset \neq S \subset N$, $v(S)$ is a nonempty closed convex subset of $\mathbb{R}^n$
- $v(S)$ is comprehensive
- $\mathbf{x} \in v(N)$ if and only if $\mathbf{x} \leq \mathbf{y}$ for some $\mathbf{y} \in H$.

Many of the properties of TU cooperative games can be translated, after suitable adjustment, into the NTU setting as well as the solution concepts (see **Cooperative Game Theory with Nontransferable Utility**).

EXTENSIONS OF COOPERATIVE GAME THEORY

In many economic applications, the number of players is so large that it is convenient to think of the players as either countably infinite or lying on some continuum I , usually identified with the interval $[0, 1]$. In the case of the continuum, the set of coalitions corresponds to a σ -algebra β of subsets of I , and the characteristic function satisfies $v : \beta \rightarrow \mathbb{R}$ where $v(\emptyset) = 0$. Differences with the finite theory emerge almost immediately. For instance, when considering the $(0, 1)$ -normalization of v , it is not appropriate to require $v(i) = 0$ because this is satisfied by, for instance, Lebesgue measure. But Lebesgue measure is additive, and this leads to a v that is not essential. Instead, the $(0, 1)$ -normalization of v is defined by the following:

- $v([0, 1]) = 1$
- $v(S) \geq \alpha$ for all $S \in \beta$
- if α is a measure such that $\alpha \leq v$ then $\alpha \equiv 0$.

The largest measure α satisfying $\alpha \leq v$ is given by $\alpha(S) = \inf \sum v(S_i)$ where the infimum is taken over all sequences of sets $S_i \in \beta$ such that $S \subset \cup S_i$. This measure is used to define the set of imputations of v when evaluating the value of a coalition. Thus, imputations are given by signed measures σ such that

$$\sigma([0, 1]) = v([0, 1]) \quad \text{and} \quad \sigma(S) \geq \alpha(S).$$

An *atom* of v is a coalition $S \in \beta$ such that $v(S) > 0$, but for all disjoint subsets $T_1 \cup T_2 = S$ either $v(T_1) = 0$ or $v(T_2) = 0$. A game v is *nonatomic* if v has no atoms. An extensive theory of nonatomic cooperative game theory has been developed for instance in Ref. 23.

Other extensions of cooperative game theory generalize the idea of a characteristic function or the way in which players participate in a coalition. Games in *partition function form* assume that the value a coalition can attain for itself depends on the coalitional structure of the remaining players. Let π be a partition of N , and let $S \in \pi$.

Then a game in partition function form is given by a real-valued function $w(S, \pi)$ which assigns to each coalition S the value it can guarantee when the players are divided into the partition π . A characteristic function for this game can be defined by

$$v(S) = \min_{\pi: S \in \pi} w(S, \pi).$$

As with NTU games, many of the properties and solution concepts of cooperative games can be extended to games in partition function form [24].

More recent extensions of cooperative game theory allow players more than two levels of participation in a coalition (either in or out of the coalition). Fuzzy games, introduced in Ref. 25, are used to model situations when players' participation in a coalition can best be described by a number $s \in [0, 1]$ where $s = 0$ corresponds to not participating at all and $s = 1$ corresponds to full participation. If participation in a coalition is interpreted as committing a quantity of resources to a cooperative project, then the intermediate levels $s \in (0, 1)$ can be interpreted as committing only a fraction of a player's full resources. A fuzzy coalition $\mathbf{s}$ in a game with N players is a vector $\mathbf{s} = (s_1, s_2, \dots, s_n) \in [0, 1]^n$ indicating each player's degree of participation. Note that every traditional coalition S is associated with the fuzzy coalition $e^S \in F^N \subset F^N$, where $e_i^S = 1$ if $i \in S$, and $e_i^S = 0$ otherwise. Let F^N stand for the set of fuzzy coalitions on N . A cooperative fuzzy game on N is a function $v : F^N \rightarrow \mathbb{R}$ such that $v(e^\emptyset) = 0$.

Similarly, there are situations when a player's ability to participate in a coalition is best described through a sequence of discrete steps. Multichoice games, introduced in Ref. 26, assume that each player i has an action space $M_i = \{0, 1, 2, \dots, m_i\}$ in which 0 corresponds to not participating and m_i corresponds to full participation. A multichoice coalition is an n -tuple $(x_1, x_2, \dots, x_n)$ where $x_i \in M_i$ for each player i . The coalitions $(0, 0, \dots, 0)$ and $(m_1, m_2, \dots, m_n)$ correspond to the empty set and the grand coalition respectively. Let $M = \prod_i M_i$ stand for the set of multichoice coalitions on N . Then, a

cooperative multichoice game on N is a function $v : M \rightarrow \mathbb{R}$ such that $v(0, 0, \dots, 0) = 0$. For good introductions to cooperative fuzzy games and cooperative multichoice games and their solutions, see Ref. 27.

COORDINATION OF PRODUCTION AND DELIVERY IN SUPPLY CHAIN SCHEDULING

ZHI-LONG CHEN

Robert H. Smith School of
Business, University of
Maryland, College Park,
Maryland

Various types of coordination in a supply chain have been studied in the literature. Examples include coordination of location, inventory, and transportation decisions [1], coordination of scheduling decisions across multiple stages of a supply chain covered in article titled ***Supply Chain Scheduling: Origins and Application to Sequencing, Batching and Lot Sizing*** in this volume, coordination of capacity allocation decisions covered in article titled ***Capacity Allocation in Supply Chain Scheduling*** in this volume, and coordination of pricing, production, and inventory decisions [2]. The coordination of production and distribution decisions are discussed in this article. Production and distribution operations can be decoupled if there is a sufficient amount of inventory between them. Some companies manage these two functions independently with little or no coordination. However, this leads to increased holding costs and longer lead times of products through the supply chain. Fierce competition in today's global market and heightened expectations of customers have forced companies to invest aggressively to reduce inventory levels across the supply chain on one hand and be more responsive to customers on the other. Reduced inventory results in closer linkages between production and distribution functions. Consequently, companies can achieve cost savings and improve customer service by coordinating production and distribution decisions.

In the past two decades, a substantial amount of research has been done on various integrated production–distribution models at the *strategic* and *tactical* planning levels

(involving decisions such as location, network design, capacity, and inventory policies (see ***Multiechelon Multiproduct Inventory Management***). Many survey articles on such models have appeared in the literature, see for example, Refs 3–5. Due to the fact that production and distribution stages at a planning level are often linked by an intermediate inventory stage, almost all of the models reviewed in those survey articles involve inventory decisions in addition to production and distribution decisions.

On the contrary, the research on coordinated production–distribution models at the *detailed scheduling* level is fairly recent; the majority of the work in this area was done in the last several years. However, this area is growing very rapidly, due to the fact that an increasing number of problems encountered in many practical settings can be modeled as a coordinated production and delivery scheduling (CPDS) problem. In a typical CPDS model, it is necessary to optimize detailed order-by-order scheduling of production and finished order delivery jointly by taking into account relevant revenues, costs, and customer service levels at the individual order level. A typical CPDS problem involves both machine scheduling (for order processing) and vehicle scheduling and routing (for order delivery). Although pure machine scheduling problems and pure vehicle routing problems have been studied extensively in the past several decades [6,7], most of the work on CPDS problems was published or done in the last decade, and a large percentage of the work was published in the last five years. Whereas many other areas of supply chain management (SCM) have been well studied, the problem area of CPDS is an exciting new area that clearly needs much more research.

This article is organized as follows: in the section titled “Application Examples” some major application examples documented in the literature are reviewed, especially those that can be modeled as a CPDS problem. In the next section titled “Problem Definition,”

the necessary notation is introduced and the common structure of CPDS problems is described. In the section on classification, existing CPDS models are classified into five major classes based on some major structural characteristics of the models and an overview is given of the existing models studied in the literature. In the section titled “Solution Methods” are discussed, in brief, the major solution techniques developed in the literature for solving these models. In the final section, several problem areas that deserve more research are pointed out. Please note that the contents of this article are mainly drawn from a recent survey paper of the author [8]; interested readers are requested to refer to that paper for more details.

APPLICATION EXAMPLES

CPDS models are often motivated by applications involving make-to-order or time-sensitive (perishable, seasonal) products where finished orders have to be delivered to customers immediately or shortly after production. Consequently, there is little or no finished product inventory in the supply chain such that production and outbound distribution must be scheduled jointly in order to achieve a desired on-time delivery performance at minimum total cost. Since the planning horizon is typically short and speedy delivery of finished orders is often critical, strategic or tactical planning models are not applicable to such applications. Instead, they require detailed scheduling models that integrate production and outbound distribution of finished orders. Examples of such applications include the following:

- *Custom-Made Electronics Products Assembly and Delivery under the Assemble-to-Order Business Model* [9,10]. In a typical assemble-to-order environment for electronics products such as PCs, customers configure their orders and assembly of components does not start until customer orders are received. To be competitive, companies often promise a very short delivery lead time (e.g., 3–5 business days), which means that assembled computers have to be delivered shortly after the assembly. Hence the assembly and delivery operations are closely linked in time.
- *Preparation and Delivery of Food in Food Catering Services* [11]. To keep food fresh, food preparation can take place only after orders are known; hence, no inventory is involved and completed orders are delivered within a few hours. Thus, production operations (i.e., food preparation) and distribution operations (i.e., delivery of completed orders to customers) are linked together directly without any intermediate step.
- *Production and Distribution of Fashion Apparel and Some Toys* [12,13]. Such products typically have a large variety and a short life cycle, and are sold in a very short selling season. Because of high demand uncertainty of the products, retailers typically do not place orders until reliable market information is available shortly before a selling season. On the other hand, because there are significant markdowns for unsold products at the end of the selling season, the manufacturer runs a high risk if it starts production early, before it receives orders from the retailers. As a result, the manufacturer does not start production until orders from the retailers have been placed shortly before the selling season. Due to the fact that there is only a limited amount of production time available, to deliver the orders to the retailers as soon as possible at a low cost, the manufacturer has to schedule the production and distribution operations in a coordinated and efficient manner.
- *Production and Delivery of Perishable Products such as Ready-Mix Concrete Paste* [14] and *Industrial Adhesive Materials* [15]. Those products have a very short lifespan. After the necessary raw materials (cement, sand, gravel, water, etc.) are mixed, the resulting concrete paste solidifies and hence becomes useless within an hour. Similarly, after production, some adhesive

materials used for plywood panels will lose their strength within seven days. So in practice, it is often required that those products be delivered to the customer site immediately after the production. Hence, the production and distribution operations are linked without any idle time between them.

- *Printing and Distribution of Newspapers* [16]. Printing of a newspaper typically starts at midnight and the printed newspaper has to be delivered to customer sites before 6:00 a.m.; to save transportation cost, orders going to different destinations are normally consolidated for delivery. However, given the short time span, each delivery truck cannot wait too long at the printing facility and may have to leave before a full truckload can be formed.
- *Mail Processing and Distribution* [17]. Mails from different origins are first sorted in a mail-processing facility, according to destination. After sorting, they are delivered by trucks to different destinations (local postal offices or other mail-processing facilities). Given the time sensitive nature of mails, there is little, if any, idle time between the sorting and delivery operations.

The products and services in the last three examples are *inherently* time sensitive. For such products and services, we *have to* consider production and outbound delivery scheduling jointly if a satisfactory performance is expected. Many other products are not inherently time sensitive, but become time sensitive under certain business environments. Fierce competition in today's global market and heightened expectations of customers have forced companies to invest aggressively to reduce inventory levels across the supply chain on one hand and be more responsive to customers on the other. As a result, an increasing number of companies now adopt make-to-order (also known as assemble-to-order, build-to-order) business models which often make the otherwise time insensitive product time-sensitive. As in the first three examples described above, products in a make-to-order environment

are often custom-made and delivered to customers within a very short lead time directly from the factory, without the intermediate step of finished product inventory. The close linkage between production and outbound distribution in many make-to-order environments makes the joint scheduling of these two operations imperative.

In addition to the close production and delivery linkage, another common characteristic seen in the production and delivery of many time-sensitive products is that orders are typically distinct and have to be processed individually and the production of an order can start only after the order is received. This is evident in most make-to-order cases where orders are custom-made and there are often such a large number of configurations or product types available for customers to choose from that it is impractical to process an order before it is received. In the case of ready-mix concrete paste and industrial adhesive materials, different orders may require different recipes and specifications and hence, have to be prepared individually. In the case of newspapers, orders destined for different customer regions often require different local contents and hence there are setups between two different orders when printing. This discrete nature of orders necessitates the detailed scheduling level consideration of order processing and delivery because treating the orders in an aggregated manner will not accurately capture the dynamics of the operations.

PROBLEM DEFINITION

First, a general CPDS problem is described and associated parameters and notation are defined, followed by a description of the common structure and characteristics shared by most CPDS problems.

A General Problem

A general CPDS problem can be described as follows. At the beginning of the planning horizon, a manufacturer which has one or more plants receives a set of n orders $N = \{1, 2, \dots, n\}$ from k ($k \geq 1$) customers $K = \{1, 2, \dots, k\}$ which may be geographically

separated. Let $N_i \subset N$ be the subset of orders destined for customer i , and $n_i = |N_i|$ for $i \in K$, where $N = N_1 \cup \dots \cup N_k$, and $n = n_1 + \dots + n_k$. The manufacturer needs to first process these orders and then deliver the finished orders individually or in batches to the customers, using $v \geq 1$ delivery vehicles (e.g., vans, trucks, and air flights). Each order $j \in N$ needs to be processed by one or multiple machines depending on the specific machine configuration involved, and has a known processing time p_j if only one machine is needed, or p_{ij} on the i th machine if multiple machines are needed. In addition, each order j may be associated with a number of parameters, including, among others, a delivery due date d_j , a size q_j which is the units of capacity needed to carry order j by a delivery vehicle, a revenue R_j if order j is processed and delivered to its customer at a desired time (e.g., before or at the deadline, within the time window), and an importance weight w_j .

The delivery vehicles may be homogeneous (i.e., have the same delivery capacity, driving speed, and cost rates) or heterogeneous (i.e., one or more parameters are vehicle dependent). The number of available vehicles may be limited or infinite, and vehicle capacity may be limited (i.e., can only carry a subset of orders in a trip) or infinite (i.e., can carry any number of orders in one trip). There are generally nonzero transportation times and nonzero variable transportation costs for traveling between different locations. There may be a fixed transportation cost associated with each shipment or each vehicle.

A *schedule* (i.e., *solution*) to a given CPDS problem consists of a *production schedule* which specifies when and where each order is processed and a *delivery schedule* which specifies how many shipments are used, the departure time and traveling route of each shipment, which orders are in each shipment, and when each order is delivered. In a given schedule, a number of measurements associated with each order can be defined, such as those given below:

C_j the *completion time* of order j , which is the time when order j 's processing is completed at the plant

S_j the *departure time* of order j , which is the time when the shipment that carries order j departs from the plant
 D_j the *delivery time* of order j , which is the time when order j is received by its customer
 T_j $\max\{0, D_j - d_j\}$, the *delivery tardiness* of order j

The objective of the problem is to optimize one or a combination of some commonly used *time-based*, *cost-based*, and *revenue-based* performance measures. Examples of such measures are given below:

Examples of Time-Based Performance Measures

- Maximum delivery time of orders, that is $\max\{D_j | j \in N\}$.
- Total (weighted) delivery time of orders, that is $D_1 + \dots + D_n$ (or $w_1 D_1 + \dots + w_n D_n$).
- Total (weighted) delivery tardiness of orders, that is $T_1 + \dots + T_n$ (or $w_1 T_1 + \dots + w_n T_n$).

Examples of Cost-Based Performance Measures

- Total trip-based transportation cost (which is the sum of the costs incurred by all individual delivery trips where the cost of a delivery trip may consist of a fixed cost and a variable cost determined by the route of the shipment, for example, total distance, independent of the total size or number of orders in the shipment).
- Total production cost of the orders (applicable when this cost varies with the production schedule of the orders).

Example of Revenue-Based Performance Measure

- Total revenue of the orders processed and delivered, that is, $\sum_{j \in A} R_j$, where A is the set of processed and delivered orders (applicable when not every order can be processed or delivered in a timely manner due to production or transportation capacity limit).

Problem Structure

Most CPDS models can be precisely defined by specifying the following four components: (i) machine configuration, (ii) delivery characteristics, (iii) number of customers, and (iv) objective function.

Machine Configuration. Most existing CPDS models involve a single production plant. In all the single-plant CPDS models, order processing at the plant follows one of the four configurations described below:

- *Single-machine* configuration where all the orders are processed by a single machine.
- *Parallel-machine* configuration where there are m identical parallel machines such that each order needs to be processed only by one of the machines.
- *Flowshop* configuration where there are m machines and each order needs to be processed by all the machines sequentially.
- *Bundling* configuration where each order consists of m independent tasks to be processed independently by m dedicated machines at the plant and the m tasks of an order are bundled together for delivery once they are all completed.

In a few existing models, there are multiple plants located at different locations such that each order needs to be processed by only one of the plants, and only the orders processed at the same plant can be delivered together. In these models, assignment of orders to plants may also be a decision in addition to production and delivery scheduling.

Delivery Characteristics. Most existing models involve homogeneous delivery vehicles, with the following vehicle characteristics (number and capacity of delivery vehicles), and delivery method.

Vehicle Characteristics: Number of Vehicles Available

- A single delivery vehicle available, that is $v = 1$.

- Multiple and finite number of vehicles available, that is $2 \leq v < n$.
- A sufficient number of vehicles available such that vehicle availability is not a constraint, that is $v \geq n$.

Vehicle Characteristics: Vehicle Capacity

- Each shipment can only deliver one order.
- Each shipment can deliver multiple orders.
- Each shipment can deliver any number of orders.
- Each shipment can deliver at most Q units of total order size (in this case, each order j occupies a generally different size of q_j units of the shipment capacity).

Delivery or Shipping Methods Allowed

- *Individual and Immediate Delivery.* Each order is shipped individually and immediately after it completes processing (i.e., $S_j = C_j$ and $D_j = C_j + t_j$ for $j \in N$, where t_j is the transportation time from the plant to order j 's destination).
- *Batch Delivery by Direct Shipping.* Only orders going to the same customer can be delivered together in the same shipment.
- *Batch Delivery with Routing.* Orders going to different customers can be delivered together in the same shipment (where vehicle routing is a part of the decision).
- *Shipping with Fixed Delivery Departure Dates.* Each vehicle has a fixed delivery departure date exactly at which the vehicle must depart from the plant; this is prespecified as a given parameter (this implies that a vehicle, if used, can cover one shipment only).

Many of the cases listed can be easily justified from a practical point of view, whereas some other cases may require explanations. The case with a sufficient number of vehicles is applicable when the delivery is handled

by a third-party logistics (3PL) provider which typically owns a large number of vehicles. The individual and immediate delivery method and the batch delivery by direct shipping method are commonly used in applications of time-sensitive products, whereas a batch delivery with routing method can be used to save transportation costs. Shipping with fixed delivery departure dates is applicable when delivery is done by a 3PL service provider which picks up customer orders at fixed times in a day (e.g., 10:00 a.m., 3:00 p.m.) which cannot be changed by the user of the service.

In most existing models with capacitated vehicles, each order is assumed to have an equal size (i.e., $q_1 = \dots = q_n$) such that the vehicle capacity is simply the maximum number of orders that can be delivered together. For such models, the vehicle capacity is such that each trip can carry either one order or multiple orders. In a handful of existing models, orders are assumed to have generally different sizes. For these models, the vehicle capacity is such that each trip can carry up to a total order size of Q units.

Number of Customers. There are one or more customers, and it is assumed without loss of generality that each customer has a distinct location so that under certain circumstances only orders destined for the same customer can be consolidated for delivery.

Objective Function. Most existing CPDS models consider one or a combination of two of the following three performance measures: customer service level, total cost, and total revenue. These measures are represented, respectively, by the time-based, cost-based, and revenue-based functions defined in the section titled “A General Problem.” The objective function is to be minimized if it is a time-based function, a cost-based function, or the sum of these two, and is to be maximized if it is a revenue-based function.

The recent survey paper [8] uses a five-field representation scheme to represent each CPDS problem precisely. For interested readers, please read the survey paper for further details.

CLASSIFICATION AND OVERVIEW OF EXISTING MODELS

Existing CPDS models can be grouped into the following five classes, according to the delivery method. The models within each class share not only major structural characteristics but also some solution properties. This enables us to discuss major commonalities of the models in each class and major differences between the models in different classes:

- models with individual and immediate delivery;
- models with batch delivery to a single customer by direct shipping method;
- models with batch delivery to multiple customers by direct shipping method;
- models with batch delivery to multiple customers by routing method;
- models with fixed delivery departure dates.

A detailed review of each class of models is given in the survey paper by Chen [8]. An overview of the existing literature is given here. Reference 18 is the first paper on a CPDS problem: the problem studied by Potts involves a single machine, multiple customers, the individual and immediate delivery method with a sufficient number of delivery vehicles, and the objective of minimizing the maximum delivery time of the orders. Most of the CPDS papers with the individual and immediate delivery method are inspired by Potts [18]. Reference 19 is the first paper that considers batch delivery and transportation costs. Many of the CPDS models with batch delivery by direct shipping method that consider transportation costs are inspired by this paper. Reference 20, which considers a variety of CPDS problems with batch delivery by direct shipping method, is the first paper that addresses transportation capacity issues. This paper has inspired many researchers to study models with transportation capacity. Since 2001, many papers have appeared, many more than that in the period from 1980 to 2000. Rapidly growing interest in the CPDS area

is believed to be motivated mainly by the following facts: (i) historically, SCM research has been almost exclusively focused on planning level decisions; (ii) an increasing number of applications (as described in the first section) now require coordinated decisions at a detailed scheduling level; and (iii) CPDS models fill in the gap between the traditional SCM research and new applications.

In addition to the delivery method and number of vehicles in a given CPDS problem, several other parameters can have a major impact on complexity and solution structure. They include number of customers (single or multiple), order sizes (equal or general), and vehicle types (homogeneous or heterogeneous). Based on these parameters, the five classes of CPDS models described earlier can be segregated into several subclasses. Table 1 gives an overview of all the models and a representative set of existing literature. Based on the current state of the literature, the following observations can be made:

- Problems with batch delivery to multiple customers and problems with fixed delivery departure dates have been studied more recently and much less extensively than problems with individual and immediate delivery and problems with batch delivery to a single customer. This is mainly because the earlier two classes of problems are more difficult to solve than the latter ones.
- Only a handful of papers consider problems with heterogeneous vehicles. In such problems, vehicles may have different speed, capacity, or/and transportation cost rates. Clearly, problems with heterogeneous vehicles are more difficult to solve than problems with homogeneous vehicles.
- Only a handful of papers study problems with multiple plants (which are generally separated geographically). In such a problem, order assignment to plants may also be a part of the decision. Clearly, problems with multiple plants are more difficult to solve than problems with a single plant.
- The majority of the existing literature studies problems where all the orders have an equal size. In such problems, the capacity of a vehicle is simply the maximum number of orders that can be carried in a shipment. This avoids the bin-packing decision that is present in the case with general order sizes. Since the bin-packing problem alone is intractable (e.g., [36]), problems with general order sizes are more difficult to solve than problems with equal order sizes.

Almost all the existing CPDS models are deterministic where all the problem parameters are known in advance. This may reflect the fact that decisions at the detailed scheduling level often involve a short planning horizon such that most information about orders is known at the beginning of the horizon. Hence, it may be sufficient to use a deterministic model.

Reference 12 is the only paper that considers models where production costs are a part of the objective function. In their models, there are multiple plants located in different countries such that the processing cost of an order depends on which plant it is assigned to, and hence it is relevant to consider the total production cost of the orders. However, in most existing CPDS problems, there is a single plant with a single machine or several identical parallel machines. Furthermore, the planning horizon is typically short such that there is little or no learning effect which is often seen in longer-term production. Consequently, the production cost of an order is fixed independent of where and when it is processed.

SOLUTION METHODS

In the CPDS literature, a small subset of problems are solved in polynomial time, mainly by dynamic programming algorithms. There are a number of problems with unknown complexity, which need to be resolved in future research. Fast heuristics based on simple rules are developed in the literature for many of the proven NP-hard

Table 1. Overview of Existing CPDS Models

	Problems by Delivery Method	Number of Customers	Order Sizes	Vehicles		Representative Literature
				Type	Number	
8	Problems with individual and immediate delivery	Multiple	Equal	Homogeneous	Sufficient	18,21–23
					Limited	14
				Heterogeneous	Sufficient	24
	Problems with batch delivery to a single customer	Single	Equal	Homogeneous	Sufficient	11,12,19,25,26
					Limited	20,26–28
			General	Homogeneous	Sufficient	29
					Limited	30,31
	Problems with batch delivery to multiple customers: direct shipping method	Multiple	Equal	Homogeneous	Sufficient	13,25,32
					Limited	9
				Heterogeneous	Sufficient	33
	Problems with batch delivery to multiple customers: routing method	Multiple	Equal	Homogeneous	Sufficient	11
					Limited	9,34
			General	Homogeneous	Sufficient	16
					Limited	15
		Multiple	Equal	Heterogeneous	Sufficient	10
			General	Heterogeneous	Limited	17,35

problems. Worst-case or/and asymptotic performance are analyzed for some of the heuristics. There are also branch-and-bound or polynomial time approximation algorithms developed for a handful of the NP-hard problems. Interested readers can find more details in the literature [8]. For fundamentals of dynamic programming and branch-and-bound algorithms, see articles titled ***Computation and Dynamic Programming*** and ***Branch-and-Bound Algorithms*** in this volume, respectively.

DIRECTIONS FOR FUTURE RESEARCH

There are a number of important CPDS problem areas for which very few results exist, and yet these problems are commonly encountered in practice. Such problems clearly deserve more research. Four such problem areas are described below:

- *Problems with Fixed Delivery Departure Dates.* Over 70% of the companies worldwide now rely on 3PL providers for their daily distribution and other logistic needs. Many 3PL service providers including major ones such as UPS, FedEx, and DHL have daily fixed package pickup times. CPDS problems in such a setting involve fixed vehicle departure dates. Only a handful of papers have studied CPDS problems with fixed delivery departure dates. Such problems tend to involve many complex issues and are generally NP-hard. One can design fast heuristics for such problems and analyze their performance.
- *Multicustomer Batch Delivery Problems with Routing Method.* In practice, the majority of deliveries by trucks involve multiple destinations, and delivery consolidation across multiple stops is commonly used to save transportation costs. Vehicle routing is an important part of the decision in such applications. Only a handful of papers have studied CPDS problems involving routing decisions. All the problems studied involve either a single vehicle or an infinite number of vehicles. It will be worthwhile to study problems with multiple but a limited number of vehicles. While vehicle routing problems with time windows have been well studied in the vehicle routing literature, few papers have considered CPDS problems with both routing decisions and time-window constraints. However, due to their practicality, such problems clearly deserve more research.
- *Problems with Heterogeneous Vehicles.* The following class of problems with heterogeneous vehicles has many applications and deserves more research. In these problems, there are several kinds of vehicles which all have the same capacity but different delivery speeds and cost rates. They can be used to model applications where delivery is carried out by a 3PL provider which offers multiple delivery modes, each with a different delivery speed and a different rate. For example, many package delivery services offer overnight, one-day, or two-day delivery, and the cost rate decreases as the delivery lead time increases. As in most 3PL applications, in such problems, there is an infinite number of vehicles available. References 24 and 10 are the only two papers that have studied such problems. One can investigate extensions from Wang and Lee's problems with other objective functions and other machine configurations.
- *Online Problems with Dynamic Order Arrivals.* In many practical make-to-order environments, orders arrive dynamically and precise information about the future orders may not be known before they are received. Therefore, the CPDS problem in such environments is often dynamic and contains some uncertainty. However, almost all the existing CPDS problems studied in the literature are static and deterministic. It is true that a static and deterministic off-line model can be used repeatedly to get a dynamic solution for such applications if the model considers all the orders that have arrived so far and is implemented on a rolling horizon basis. However, such an approach can

be very time consuming and difficult to use in a real-time fashion. An alternative and more practical approach would be on-line algorithms based on simple rules which can be implemented in real time. It will also be interesting to study performance (e.g., competitive ratio) of such algorithms theoretically.

COST-EFFECTIVENESS ANALYSIS, HEALTH-CARE POLICY, AND OPERATIONS RESEARCH MODELS

GREGORY S. ZARIC
Ivey School of Business,
University of
Western Ontario, London,
Canada

INTRODUCTION

Cost-effectiveness analysis (CEA) provides a formal process to evaluate the trade-offs between the incremental costs and the incremental benefits associated with adopting a new medical technology. Throughout this article, we shall use the terms “medical technology” and “intervention” to refer to a drug, device, policy, procedure, or anything else that can improve the health of individuals or populations. Starting in the early 1990s with Ontario and Australia, many public sector drug plans have formally required that CEA be used as part of their decision-making process regarding funding and reimbursement decisions for new drugs. This requirement has become common enough that it is now referred to as *the fourth hurdle* [1] (the other three hurdles for drug approval are safety, efficacy, and manufacturing quality).

CEA often involves complex mathematical modeling. This includes decision-analytic models, Markov models, Monte Carlo simulation models, and dynamic compartmental models. In addition, incorporating this information into health policy decisions involves complex organizational processes and structures. The purpose of this article is to provide an overview of CEA and its role in health policy. In the next section, we shall briefly introduce CEA. In the section titled “Models Used in Cost-Effectiveness Analysis” we will describe some of the models commonly used in CEA. In the section titled “Role in Public Policy Decisions”, we shall give a brief

overview of how CEA is used in health-care policy, focusing on Ontario, the United Kingdom, and the United States.

COST-EFFECTIVENESS ANALYSIS

CEA typically involves the construction and interpretation of the incremental cost-effectiveness ratio (ICER). The ICER for a new medical technology is defined as follows:

$$\text{ICER} = \frac{\text{Cost}_{\text{New}} - \text{Cost}_{\text{Old}}}{\text{Health}_{\text{New}} - \text{Health}_{\text{Old}}} = \frac{\Delta C}{\Delta H}.$$

In the equation above, Cost_{New} and Cost_{Old} are the average future lifetime costs for a cohort receiving the new and old technologies, respectively; $\text{Health}_{\text{New}}$ and $\text{Health}_{\text{Old}}$ are the average future lifetime health experienced by a cohort receiving the new and old technologies, respectively. Thus, the ICER gives the incremental cost (ΔC) associated with switching to the new technology per unit of incremental health benefit (ΔH) associated with switching to the new technology. The definition of “Old” is not uniformly agreed upon, with some arguing that it should be the best possible standard of care (not including the new technology) and others arguing that it should reflect a mix of all treatment options currently used. It is, however, generally agreed that “Old” should not mean “no treatment” unless there really is no other alternative since this comparison could produce overly optimistic ICER estimates. This technique can be easily extended to comparisons among multiple interventions. In that case, the ICER is calculated on the basis of a comparison of each intervention relative to the next best alternative.

In some instances, health is measured in disease-specific units (e.g., change in viral load, symptom-free days gained, and change in a disease severity index). However, the preferred measure of benefit in CEA is quality-adjusted life years (QALYs) of survival gained [2]. QALYs are life years that have been scaled between zero (representing

death) and one (representing perfect health) according to the utility associated with the health state. QALYs reflect the notion that years of life lived in some health states are less desirable than years of life in other states. For example, one estimate places the quality of life adjustment for asymptomatic HIV at 0.80 and for major AIDS-defining illness at 0.42 [3]. If quality of life adjustments are not available, which is often the case for conditions involving pediatrics or mental health, then life years of survival are the preferred alternative.

There are three main types of tools for estimating the quality of life associated with a health state: utility-based measures, such as the standard gamble and time trade-off; rating scales, such as the visual analog scale; and multiattribute scores, such as the Health Utilities Index (HUI), EuroQoL, SF-36 and SF-12, as well as numerous disease-specific quality of life measures. The utility-based measures are generally preferred on theoretical grounds, but the multiattribute instruments, which are short survey questionnaires, are much easier to use in research studies.

In the equation for the ICER, the “Cost” and “Health” terms are defined as future lifetime costs and health, respectively. These terms are calculated as the integral of the time spent in each health state until death, weighted either by the cost or the quality of life of each health state for “Costs” and “Health,” respectively. It is common practice to discount future costs and health, with discount rates of 3–5% being suggested by some cost-effectiveness guidelines [4].

If health outcomes are measured in life years or QALYs, then the ICERs for interventions that treat different diseases are expressed in common units like “cost per life-year gained” or “cost per QALY gained.” This allows one to compare the ICERs for interventions that treat different conditions. If health is measured in disease-specific outcomes, then it may be impossible to compare across different conditions. Finally, a comment on terminology: the term “incremental cost utility ratio” (ICUR) is occasionally used to distinguish an ICER in which QALYs are

the measure of health outcome from one in which some other measure is used.

Interpreting Cost-Effectiveness Ratios

Stating that something is or is not cost effective involves making a value judgment about whether the costs of a new technology are justified by the benefits. Some insight about ICER values can be gained by plotting them in the cost-effectiveness (C-E) plane (Fig. 1). In the C-E plane, incremental costs are plotted along the vertical axis and incremental health benefits are plotted along the horizontal axis (some authors present the C-E plane with the axes reversed). A common interpretation is that technologies in the lower right quadrant are cost saving and should always be adopted. They produce positive health benefits at negative costs. Technologies in the upper left quadrant are more expensive and less effective than the existing technology. These are said to be “dominated” and should never be adopted. Technologies in the upper right quadrant are more expensive and more effective than the existing technology and will have positive ICER values. Determining whether they are cost effective involves a value judgment. Technologies in the bottom left quadrant also have positive ICER values and involve value judgments. However, adopting them involves a difficult policy decision because it would mean switching to something that is both less expensive and less effective than the current standard of care.

Two methods that can assist with making the value judgments required with positive ICER values are comparing them versus a fixed willingness-to-pay (WTP) threshold and listing them in a league table. In the United States, a fixed WTP threshold of \$50,000/QALY gained is often used or implied [5]. The \$50,000/QALY threshold is thought to be based on the cost effectiveness of renal dialysis for end stage liver disease, as assessed in the 1970s [6]. There is currently a spirited debate about whether this figure is appropriate, with some arguing that it may be too high [7], others arguing that it is too low and should be inflation-adjusted to reflect current prices [8], and others arguing that threshold interpretations should not be used at all [9].

Figure 1. The cost-effectiveness plane.

In Canada, a range WTP threshold values has been suggested, with values less than \$20,000/QALY gained being considered to have strong evidence for adoption, those above \$100,000/QALY gained having weak evidence for adoption, and those in between requiring judgment calls [10]. A review of UK National Health Service (NHS) decisions found an implied threshold of £30,000/QALY [11], a value that has also been reported in the British press [12]. For developing countries, a benchmark of three times GDP per capita has been suggested as a definition of “cost effective” [13].

The second method of interpreting ICERS involves a comparison of ICER values in a league table [e.g., Ref. 14; a sample league table is shown in Table 1]. This method may help with decision making by providing an inferred WTP for other similar technologies.

Justification for Cost-Effectiveness Analysis

The use of CEA in policy decisions is often justified by considering marginal expenditures. A policy maker with only \$1 left in her budget may be confronted with a “menu” of n interventions having ICER values $r_1, r_2, \dots, r_n$. Inverting the ratios gives the incremental health benefits purchased per dollar spent. It is clear that the policy maker would purchase the most health-care benefits for that \$1 (the most “bang for the buck”) by investing in the program with the smallest ICER. (It is also clear that this comparison is impossible

to make if the n different programs use n different measures of health benefits.)

An alternate justification of using CEA is based on its relationship to an optimization problem. Suppose that a planner with a budget B can invest in n different health-care programs. Let x_i be the number of units of program i , let h_i be the incremental health benefit per unit of program i purchased, and let c_i be the cost per unit of program i , $i = 1, \dots, n$. Let U_i , $i = 1, \dots, n$, be an upper limit on the number of units of program i that can be purchased. We index the programs so that the ratios c_i/h_i (the cost-effectiveness ratios of each program) are increasing in i . Assuming that the costs and benefits scale linearly and that the programs do not interact with each other, the investment problem can be written as the following linear program (LP):

$$\begin{aligned} \max \quad & \sum_{i=1}^n h_i x_i \\ \text{s.t.} \quad & \sum_{i=1}^n c_i x_i \leq B, \\ & 0 \leq x_i \leq U_i, \quad i = 1, \dots, n. \end{aligned}$$

This is a “knapsack” LP and it is straightforward to show that the optimal solution is found by investing as much as possible in the set of programs with the lowest ICERs; investing an intermediate amount in one program; and investing nothing in the programs

Table 1. League Table with Some Recent Cost-Effectiveness Estimates

Intervention	Country	ICER Estimate	Source
Letrozole versus tamoxifen as initial adjuvant therapy in postmenopausal women	Canada	\$23,662/QALY gained	15
Colorectal cancer screening in renal transplant recipients	USA	\$22,309 per life-year gained	16
Influenza vaccination in working-age cancer patients	USA	\$224/QALY gained	17
Open versus laparoscopic living-donor nephrectomy	USA	\$1,693,733 per QALY	18
Prevention strategies for gynecologic cancers in Lynch syndrome	USA	\$194,650/QALY gained versus prophylactic surgery at age 40	19
Hepatitis B vaccination in low income countries	The Gambia	US\$28 per disability-adjusted life-year (DALY) averted	20
Cotrimoxazole prophylaxis in HIV-infected children	Zambia	US\$72/LY gained US\$94/QALY gained US\$53/DALY averted	21

with the highest ICERs. More formally, define an index k such that $\sum_{i=1}^{k-1} U_i < B$ and $\sum_{i=1}^k U_i \geq B$. Then $x_i = U_i$, $i = 1, \dots, k-1$; $x_k = B - \sum_{i=1}^{k-1} U_i$; and $x_i = 0$, $i = k+1, \dots, n$. When written this way, the value c_k/h_k can be interpreted as the threshold WTP. Several authors have discussed similar mathematical programming formulations [22].

Note that the LP formulation described above represents a simplified version of the problem in which none of the interventions are dominated. A more general formulation in which there are dominated interventions that must be removed from consideration before solving has been presented elsewhere [23]. The authors show that selecting interventions in increasing order of cost-effectiveness ratios remains optimal in this more general setting.

MODELS USED IN COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness estimates are commonly derived from two sources: clinical trials

and mathematical models. To obtain cost-effectiveness estimates from clinical trials, patients are randomized to different trial groups as in a normal clinical trial. Costs would then be tracked along with health outcomes, and this data used in constructing cost-effectiveness estimates (see Ref. 24 for details).

Although the method just described can be used to generate ICER estimates from trials, many (perhaps most) ICER estimates are derived from mathematical models. Models are used for several reasons: trials typically take place over a short time horizon, like weeks or months, whereas a cost-effectiveness estimate requires an estimate of the impact of the intervention on lifetime health and health-care costs; trials typically evaluate the impact of a technology on a single parameter, whereas a cost-effectiveness estimate may require understanding the impact of changes in multiple parameters, with data derived from several trials; it is uncommon to gather cost information as part of RCTs; some CEAs involve comparing multiple different interventions which, by definition, would

require synthesis of evidence from multiple trials; and trial data is not always available. In the remainder of this section, we present several types of models commonly used in CEA.

Decision Trees

Decision-tree models are used to illustrate a sequence of uncertain events, including survival, infection status, time of detection, adverse events, and anything else relevant in the calculation of the ICER, following a decision about whether to use a new technology. Figure 2 shows a sample tree for a simple case of two outcomes, “cured” and “not cured.” In this example, the differences between the technologies are the probability of the patient being cured and the cost of the technology itself. More realistic models would likely indicate differences in many other factors resulting in a more detailed

tree structure. Tree models are often used to evaluate technologies that involve a short, one-time application of the technology. This includes screening programs, such as screening newborns for genetic diseases [25]; diagnostic strategies [26]; and treatment of short-term acute infections [27].

Markov Models

Markov models are commonly used to model disease progression for long-term chronic conditions in which patients progress through a number of different health states. Figure 3 depicts a representative model. These models have been used to analyze hepatitis [28], diabetes [29], rheumatoid arthritis [30], and many other diseases. These models assume the Markovian property that the probability of transitioning to a new health state depends only on the current state and not the entire history. If the Markovian property is

$$\text{ICER} = \frac{E[\text{Cost}_{\text{New}}] - E[\text{Cost}_{\text{Old}}]}{E[\text{Health}_{\text{New}}] - E[\text{Health}_{\text{Old}}]}$$

Figure 2. A representative decision tree.

Figure 3. A representative Markov model.

not satisfied, then there are several modeling tricks that can be used to create a Markov model. However, the resulting model may contain a very large number of states.

Markov models often include “dead” as an absorbing state. The other states can be based on symptoms, disease status (e.g., tumor stage in a cancer model, viral load in an HIV model), or other factors. For long time horizons, the probability transition matrix is likely nonhomogeneous because death rates vary with age. The transition probabilities at each time step can be estimated from life tables and adjusted using odds ratios and relative risks derived from clinical trials.

It is common to use Markov models to estimate the ICER for a cohort of individuals rather than to simulate the experience of large numbers of individuals. Under this approach, a cohort will be initially distributed across model compartments (with a special case being all individuals initially in the same compartment). The cohort will be followed either for a long period of time (like 100 years) or until all members of the cohort are dead. When used in this way, Markov models are deterministic: the same cohort will always produce the same expected cost and the same expected health.

Markov models are often used in conjunction with decision-tree models. In this approach, a tree will be used to model a short-term sequence of events and Markov models are used to estimate the expected health and cost components at the ends of the tree [31].

Markov Decision Process Models

In Markov decision processes, a patient’s health status is modeled as a Markov process. A key difference compared to Markov models is that, at each time step, patients make an optimal decision about their treatment which can have the effect of moving them to a different health state, whereas in Markov models patients transition between health states based only on the state transition matrix. These models have been used to model optimal decisions regarding statin therapy treatment strategies [32], HIV treatment [33], and acceptance or rejection decisions for patients waiting for liver transplants [34].

Monte Carlo Simulation Models

If the Markovian property is not satisfied or if the level of complexity exceeds that which can be easily incorporated into a Markov model, then Monte Carlo simulation models are often used. For example, it may be important to model drug resistance in a model of HIV because drug resistance may have an impact on treatment success and hence disease progression. Since drug resistance is based on treatment history, the Markovian property would be violated.

There are two general types of Monte Carlo simulation models: first order and second order. First order models, also known as *microsimulation models*, simulate the lives of individual patients and therefore capture variability between patients. Second order models capture parameter uncertainty

and are typically used to conduct stochastic sensitivity analysis (described in more detail below).

Two well-known Monte Carlo models are the cost effectiveness of preventing AIDS complications (CEPAC) model [35] and the Archimedes model [36,37]. The CEPAC model is a detailed model of HIV progression which simulates at the level of individual patients. For each patient, the model tracks CD4 count, viral load, and history of opportunistic infections, and uses this information to predict disease progression and the occurrence of opportunistic infections. The model is commonly used to estimate the cost effectiveness of HIV treatment options. The Archimedes model simulates organs (e.g., heart, lungs, and kidneys) and biological processes, and then uses this simulated information to simulate the lives of individual patients. The Archimedes model could be used to estimate the cost effectiveness of a new drug by incorporating information about the impact of that drug on various metabolic processes.

As can be imagined, Monte Carlo models are computationally intensive and variability between patients may be high. In the case of the CEPAC model, it is common to simulate 2–5 million patients per scenario [38]. In the case of the Archimedes model, simulation takes place over a distributed network [39].

Compartmental Infectious Disease Models

A special type of compartmental model is often used to estimate the cost effectiveness of technologies where a significant benefit is the prevention of a communicable disease. In these models, the population is

segmented into a number of discrete groups (compartments), which are typically defined by health or behavior. One set of health states represents uninfected individuals and another set represents infected individuals.

A distinguishing feature of this type of model is that the rate of acquiring new infections is proportional to the product of the number of infected individuals and the number of susceptible individuals. This corresponds to a random mixing assumption. If S and I represent the total numbers of susceptible and infected individuals, respectively, then for each susceptible individual the probability that a new encounter, selected randomly, is with an infected individual is $I/(S + I)$. Encounters between susceptible and infected individuals are the only types of encounters that can result in infection transmission. The total number of this type of encounter is $S \times I/(S + I)$. Since the number of individuals in each compartment is constantly changing (i.e., S and I are functions of time), the rate of acquiring new infections is also constantly changing. In models with multiple risk groups, it is possible to incorporate preferential mixing [40,41]. However, within a given type of encounter (e.g., injection drug users with heterosexual nondrug users) the mixing is still random.

Figure 4 shows a representative four-compartment model where the population is divided into groups based on risk behavior (high risk vs low risk) and infection (infected vs not infected). The movement of the population through the set of compartments is indicated by the arrows in Fig. 4. This movement is formally described by a system of

Figure 4. A representative compartmental model for simulating a contagious disease.

nonlinear differential equations constructed using standard principles [42].

These models have been used to evaluate the cost effectiveness of a number of interventions related to HIV including expanding methadone treatment [40] and expanding access to antiretroviral treatment [43]. They have also been used to evaluate vaccination strategies for numerous diseases including those for hepatitis A [44], HPV [45], and varicella [46].

Sensitivity Analysis

CEA models are subjected to extensive sensitivity analysis including one-way, multiway and probabilistic analyses. In one-way and multiway sensitivity analyses, one or more parameters are varied within reasonable ranges and the ICER value is reported as a function of these parameters. A variant of this approach is to report whether the ICER exceeds a WTP threshold for any value with the range. There are many ways to define the range for this type of sensitivity analysis: if a single study or trial is used to estimate a parameter value, then the confidence interval associated with that trial could be used; if multiple trials are considered, then the range of estimates across all trials might be used; if a formal meta-analysis of several trials has been conducted, then the confidence interval associated with that analysis could be used; and in the absence of good trial data, expert opinion could be used.

Many CEA models contain a large number of parameters, making it difficult to describe the simultaneous sensitivity of a model to all parameters in a multiway analysis. Probabilistic sensitivity analysis (also called second order Monte Carlo simulation) has emerged as a way to handle this situation. In probabilistic sensitivity analysis, a prior distribution is defined for each model parameter. The prior distributions may be informed using the same techniques used to determine reasonable ranges for one-way sensitivity analysis. Probabilistic sensitivity analysis is carried out by treating each model parameter as a random variable, drawing a complete set of parameter values, calculating the incremental cost and the incremental effectiveness given the set of parameter values,

and repeating a large number of times. Outcomes for each set of parameter values can be plotted on the C-E plane to give a sense of dispersion in C-E space. This type of sensitivity analysis is frequently used with decision-tree models, Markov models, and compartmental models, but not with Monte Carlo models because of computational intensity.

The cost-effectiveness acceptability curve (CEAC) can be used to interpret the results of probabilistic sensitivity analysis. A representative diagram is shown in Fig. 5. Figure 5a shows sample output plotted in the C-E plane, along with three threshold WTP values, and Fig. 5b shows the CEAC generated from this output. The CEAC is a graph with the WTP threshold along the x -axis and the probability that the intervention is cost effective along the y -axis. It thus shows, for each possible value of the societal WTP threshold, the probability that the intervention should be adopted for funding. Note that the CEAC need not converge to zero (for small WTP) or one (for high WTP) if some of the simulated results fall outside of the northeast quadrant of the C-E plane, as is shown in Fig. 5 and noted elsewhere [47]. From the perspective of the analyst, an advantage of this method is that it does not require any assumptions to be made about a specific WTP value. However, the policy maker who interprets the analysis is not spared from this requirement.

A relatively new tool for sensitivity analysis is value of information analysis [48]. Value of information analysis is a framework similar to the concept of “expected value of perfect information.” In this approach, two ICER values are compared: one derived from a probabilistic sensitivity analysis of the model, and a second, also from a probabilistic sensitivity analysis, but assuming that one or more parameters describing the effectiveness of the new technology are known with certainty. The comparison highlights for decision makers whether they should expect there to be any benefit from additional research [49–51]. If there is no benefit to additional research, then a clear recommendation can be made even in the presence of significant uncertainty.

Figure 5. Probabilistic sensitivity analysis and a cost-effectiveness acceptability curve. (a) Sample output from a probabilistic sensitivity analysis showing results plotted in the upper right quadrant of the C-E plane. The three lines correspond to WTP thresholds of \$20,000, \$50,000, and \$100,000. (b) The resulting cost-effectiveness acceptability curve.

There are some difficulties in applying probabilistic sensitivity analysis, and consequently, in conducting value of information analysis. One problem is choosing an appropriate prior probability distribution. This can be particularly difficult if the parameter

estimates were obtained from secondary sources which only presented summary statistics such as a mean and standard deviation. A second problem is that correlations between model parameters are almost never reported. Thus, many analysts assume a

joint distribution in which all parameters are independent, which is unlikely to be true.

ROLE IN PUBLIC POLICY DECISIONS

In many countries, CEA has been formally integrated into health-care policy decision making, and, in particular, in pharmaceutical policy making. A common application is in assisting with formulary decision making. A formulary is a list of drugs that will be reimbursed by an insurance provider. Formulary listing is very important for drug manufacturers because, if a drug is not listed, then patients have a financial incentive to substitute for a similar product that is listed and hence reimbursed by their drug plan. For instance, there are many statins, ACE inhibitors, and migraine medications (to name just a few examples) on the market but not all are approved by all insurance plans. In addition to listing the drugs, a formulary may contain “Limited Use” conditions which are conditions under which each drug can be used. Common types of limited use conditions include restriction to a single use for a product that has many potential uses and restriction of use to cases where a patient has previously experienced failure or toxicity with another drug.

Ontario and Australia are generally recognized as the first jurisdictions to have formally incorporated CEA into their processes for approving new drugs [1,52]. Guidelines for evaluating pharmaceutical products were issued in Ontario in 1991 and in Australia in 1993 [52]. In the remainder of this section, we give a brief overview of the integration of CEA with pharmaceutical policy in Ontario, the United Kingdom, and the United States.

Ontario, Canada

In Ontario, the Ontario Drug Benefits (ODB) Plan is a public drug insurance plan for prescription drugs for people over the age of 65 as well as for low income and special needs populations. Prescription drugs for people not in these groups are paid for privately, either as an out-of-pocket expense or from

a private drug plan. In addition to ODB, Cancer Care Ontario maintains a formulary for cancer drugs and hospitals maintain their own formularies for drugs used by inpatients. Private insurance plans also maintain their own formularies.

A simplified description of the process for a drug to get listed on the formulary in Ontario is as follows:

1. The drug must receive regulatory approval from Health Canada, which evaluates safety and efficacy.
2. The manufacturer must receive pricing approval from the Patented Medicine Prices Review Board (PMPRB) which reviews the “factory gate price” (the price charged by the manufacturer to pharmacies, hospitals, and wholesalers) “to ensure that they are not excessive.”
Following step 2, drugs can be marketed and sold in Canada. However, this does not guarantee that public or private insurance plans will reimburse their use.
For a drug to be added to the ODB formulary there are four additional steps:
3. The drug is reviewed by the Common Drug Review (CDR). CDR looks for evidence of effectiveness (performance in real-world settings as opposed to clinical trial conditions) and cost effectiveness relative to current accepted treatments.
4. The Canadian Expert Drug Advisory Committee (CEDAC) considers the CDR review and makes a recommendation for the provincial formularies in one of three categories: fund, do not fund, or fund with conditions.
5. The CDR review and CEDAC recommendations are sent to the Ontario’s Ministry of Health and Long-Term Care Committee to Evaluate Drugs (CED). In addition to evidence of effectiveness and cost effectiveness, CED requires an estimate of budget impact for the formulary if the drug is approved.
6. The CED makes a recommendation to the executive director, who then makes

a decision about adding the drug to the ODB formulary. The executive director may engage in negotiations with the drug manufacturer regarding price or risk-sharing agreements before adding the drug to the formulary.

The process outlined above is used for new drugs as well as for new uses of existing drugs. Cancer drugs follow a similar process with some exceptions. There is no fixed or generally adhered to process for hospital formulary decision making, and the processes range from ad hoc to very formal depending on the institution.

How are cost-effectiveness models incorporated into this process? The drug manufacturer submits a CEA in the form of a published article from a peer-reviewed journal or an unpublished report. The CEA is formally reviewed by CDR in step 3 and by CED in step 5. CDR requires that the manufacturer submit an electronic copy of the model (e.g., the spreadsheet model or a model prepared in a speciality package like TreeAge) to allow the reviewers to conduct their own sensitivity analysis or change base case parameter estimates if necessary.

What information do the decision makers and reviewers look for in the models? In Ontario, there is a template to assist in the review of the economic models; versions of this template have been published in academic journals [53]. Much of the template addresses important modeling issues, such as establishing model validity, conducting sensitivity analysis, and conducting subgroup analysis, as well as questions on the importance of quality of life assumptions. In addition to technical model questions listed above, the template asks “Does the cost of the therapy justify the clinical and/or quality of life outcomes relative to comparators?” This question forces the reviewers to make a value judgment (in effect, a policy recommendation) based on the model results. One can argue at length about the pros and cons of league tables, fixed WTP thresholds and other decision-making heuristics. However, each newly approved drug represents a policy decision that must be made.

Is there evidence that the models are used in decision making? CEDAC publishes short memos on-line outlining their recommendations [54]. Recommendations for or against funding can be made for a number of reasons, but considerations related to CEA are often cited. For example, for varenicline (Champix/Chantix), the CEDAC recommendation in favor of adoption included the following statement about cost effectiveness: “While this evaluation was based on a number of assumptions, the Committee felt that varenicline was cost effective...” [55]. In the case of zoledronic acid (Alclasta and Zometa), CEDAC recommended against formulary listing. In their recommendation, they stated “...zoledronic acid was not found to be cost effective when compared to oral bisphosphonate agents.” [56]

The United Kingdom

In the United Kingdom, the National Institute for Clinical Excellence (NICE) was established in 1999 to provide guidance to the NHS regarding medical technologies. As with the evaluation process in Canada, recommendations by NICE often include CEA evidence. Readers seeking a detailed description of health technology assessment in the United Kingdom are referred elsewhere [57,58]. Here, we highlight two key differences between the process used by NICE and the process described above for drugs in Canada.

- The formulary in Canada is known as a *positive list* in which drugs must be approved in order to be listed. The United Kingdom maintains a “negative list” which lists drugs that cannot be used. If a drug has not been reviewed by NICE, then there are no restrictions on its use and funding decisions are made by the regional primary care trusts.
- In Canada, the CEA models are supplied by the drug manufacturers. The reviewers assess the evidence provided by the manufacturers. In the United Kingdom, CEAs are commissioned from

an academic medical center. The models are produced independently of the drug manufacturers but may include data provided by the manufacturers such as unpublished data from registries or clinical trials.

Is there evidence that CEA is used as part of the decision-making process? NICE recommendations frequently contain extensive details about the cost-effectiveness modeling that was done to support their recommendation. There has been academic work in the form of case studies to assess the impact of CEA on NICE decisions [59,60]. Additionally, decisions by NICE are often reported in the press. In 2008, the *Times* reported that NICE had recommended against funding four cancer drugs—sunitinib (Sutent), bevacizumab (Avastin), sorafenib (Nexavar), and temsirolimu (Torisel) [12]. The article quotes the public health director of NICE as saying “Although these treatments are clinically effective, regrettably the cost to the NHS is such that they are not a cost-effective use of resources.” [12] However, in February 2009, NICE reversed its recommendation for sunitinib after the manufacturer and the NHS developed a risk-sharing agreement to reduce the cost in patients who do not respond to treatment [61]. In 2007, the BBC reported that “Early in 2007, the drugs watchdog NICE said the drug Alimta was not cost effective.” [62] However, public policy decisions involve more than considerations of technical efficiency, and the same article later states “But groups and sufferers in the North East successfully lobbied to get that decision overturned and the drug is now available.” [62]

The United States

It is easy to find examples of CEA influencing policy in the United Kingdom, Canada, and other places where public insurers have issued guidelines about the use of CEA. Examples in the United States are less obvious, and many have speculated about why this is the case. Luce [63] suggests five categories of reasons: skepticism with methods, potential lack of training by decision makers, legal problems, trust

problems, and political issues related to the perceived relationship between “cost effectiveness” and “rationing.” Grosse *et al.* report that CEAs helped change the recommendations regarding the frequency of cervical cancer screening, although the change in recommendations may not have led to a change in practice [64]. CEA has been cited in guidelines issued by the US Centers for Disease Control and Prevention (CDC). For example, a recent update to the CDC guidelines on HIV screening [65] refers to three cost-effectiveness analyses [38,66,67]. Recent CDC guidelines on hepatitis B identification and management [68] also refer to a CEA [28]. Clinical practice guidelines issued by various medical associations occasionally refer to CEAs. However, these are guidelines and not binding policy mandates.

In 2009, as part of the US Recovery Act, \$1.1 billion was allocated to comparative effectiveness research (CER), to be distributed through three government funding agencies [69]. The interpretation of CER and the allocation of these funds has generated some controversy [70,71].

LIMITATIONS

There are limitations to CEA. The technique may not do a good job at capturing preferences for equity by decision makers. Kaplan and Merson [72] and Zaric and Brandeau [73] have developed models to investigate equity-efficiency trade-offs in the allocation of HIV prevention resources. Some have argued that reliance on CEA might bias funding away from expensive drugs that treat very rare conditions [74]. Such decisions may not reflect societal values. For example, some enzyme replacement therapies cost more than \$300,000 per year, but if they are not funded patients may have few alternatives. The experience in the United Kingdom has illustrated the importance of political considerations in funding decisions. And, as mentioned earlier, some decision makers may be resistant to using CEA, for a variety of reasons [63].

CONCLUSIONS

In this article, we briefly discussed CEA, some of the mathematical models that are used in CEA, and how CEA is used in health-care policy decisions in Canada, the United Kingdom and the United States. Similar processes are used elsewhere, including Australia, New Zealand [57], and much of Europe [75]. It has recently been reported that recommendations made by NICE in the United Kingdom influence decisions in several other countries [76].

The growing acceptance of these models by policy makers combined with the rapid pace of development of new medical technologies will likely create increased demand for this type of research. In addition, advances in computing power and simulation theory may drive the ability to develop increasingly sophisticated large-scale simulation models. For operations researchers, this field represents a great opportunity to become engaged in an important, growing body of research that involves sophisticated models developed by interdisciplinary research teams, and that has the potential for real-world impact.

Science, Lancaster University,
Lancaster, UK

Many problems arising in OR/MS can be formulated as *mixed-integer linear programs* (MILPs): see the article titled **Formulating Good MILP Models** in this encyclopedia. If one wishes to solve a class of MILPs to proven optimality, or near optimality, it is often useful to have a class of *cutting planes* available. Cutting planes are linear inequalities that are satisfied by all feasible solutions to the MILP, but may be violated by solutions to its continuous relaxation (see **Branch and Cut**).

This article is concerned with one particular class of cutting planes—the *cover inequalities*—along with some variants of them. Cover inequalities were originally defined in the context of the *0–1 Knapsack problem* (0–1 KP), but can be applied to any *0–1 linear program* (0–1 LP). Moreover, the idea underlying the cover inequalities has been extended to yield cutting planes for other knapsack-type problems and other kinds of MILPs.

The article is structured as follows. In the section titled “Theory,” we recall the theory underlying the inequalities. In the section titled “Algorithmic Aspects,” we discuss some algorithmic questions that must be addressed if one wishes to actually use cover inequalities in a cutting-plane algorithm. In the section titled “Applications,” we list some of the problems to which cover inequalities have been applied. Finally, at the end of the article, we give some pointers for further reading.

THEORY

Knapsack Polytopes

As mentioned above, the cover inequalities were first presented in the context of the 0–1 KP. The 0–1 KP takes the following form:

$$\max \left\{ p^T x : w^T x \leq c, x \in \{0, 1\}^n \right\}.$$

Here, $p \in \mathbb{Z}_+^n$ is the vector of *profits*, $w \in \mathbb{Z}_+^n$ is the vector of *weights* and $c \in \mathbb{Z}_+$ is the *knapsack capacity*.

The convex hull of feasible solutions to a 0–1 KP, that is, the set

$$\text{conv} \left\{ x \in \{0, 1\}^n : w^T x \leq c \right\},$$

is called a *knapsack polytope*. We will let $KP(w, c)$ denote this polytope. In theory, the strongest possible cutting planes, for a given w and c , are those that define *facets* of $KP(w, c)$ (see **Basic Polyhedral Theory**).

Cover and Extended Cover Inequalities

Now, let N denote $\{1, \dots, n\}$. A set $C \subset N$ is called a *cover* if it satisfies $\sum_{j \in C} w_j > c$. Since it is impossible to set all of the variables in C to 1 simultaneously while maintaining feasibility, the linear inequality $\sum_{j \in C} x_j \leq |C| - 1$ is valid for $KP(w, c)$. This is the *cover inequality* (CI).

The CIs were introduced independently by Balas [1], Hammer *et al.* [2], and Wolsey [3]. These authors observed that the strongest CIs are obtained when the cover C is *minimal*, in the sense that no proper subset of C is also a cover.

A simple way to strengthen the CIs was given by Balas [1]. Compute $w^* := \max_{j \in C} w_j$ and define the *extension* of C as $E(C) := C \cup \{j \in N \setminus C : w_j \geq w^*\}$. The *extended cover inequality* (ECI) $\sum_{j \in E(C)} x_j \leq |C| - 1$ is then easily seen to be valid for $KP(w, c)$.

Example. Suppose that $n = 8$ and that the knapsack constraint takes the form $4x_1 + 6x_2 + 6x_3 + 6x_4 + 6x_5 + 7x_6 + 8x_7 + 15x_8 \leq 22$. The set $\{1, 2, 6, 7\}$ forms a cover, since $4 + 6 + 7 + 8 = 25 > 22$. Moreover, it is a minimal cover. The corresponding CI takes the form $x_1 + x_2 + x_6 + x_7 \leq 3$. Moreover, we have $w^* = 8$ and $E(C) = \{1, 2, 6, 7, 8\}$, and therefore, the corresponding ECI takes the form $x_1 + x_2 + x_6 + x_7 + x_8 \leq 3$.

Although the ECIs dominate the CIs, they are still not guaranteed to define facets of $KP(w, c)$, as explained in the next section.

Lifted Cover Inequalities

Balas [1] and Wolsey [3] showed that, given any minimal cover C , there exists at least one facet-defining *lifted cover inequality* (LCI) of the form

$$\sum_{j \in C} x_j + \sum_{j \in N \setminus C} \alpha_j x_j \leq |C| - 1, \quad (1)$$

where $\alpha_j \geq 0$ for all $j \in N \setminus C$. Moreover, each such LCI dominates the ECI.

Example (continued). From the given cover $\{1, 2, 6, 7\}$, one can derive the following four LCIs:

$$\begin{aligned} x_1 + x_2 + x_3 + x_6 + x_7 + 2x_8 &\leq 3 \\ x_1 + x_2 + x_4 + x_6 + x_7 + 2x_8 &\leq 3 \\ x_1 + x_2 + x_5 + x_6 + x_7 + 2x_8 &\leq 3 \\ x_1 + x_2 + \frac{1}{2}x_3 + \frac{1}{2}x_4 + \frac{1}{2}x_5 + x_6 \\ &\quad + x_7 + 2x_8 \leq 3. \end{aligned}$$

Each of these LCIs clearly dominates the ECI, and all of them can be shown to define facets of $KP(w, c)$.

Note that a facet-defining LCI can have fractional coefficients.

Van Roy and Wolsey [4] noted that one can derive more general LCIs of the form:

$$\begin{aligned} \sum_{j \in C \setminus D} x_j + \sum_{j \in N \setminus C} \alpha_j x_j + \sum_{j \in D} \beta_j x_j &\leq |C \setminus D| \\ &\quad + \sum_{j \in D} \beta_j - 1, \end{aligned} \quad (2)$$

where C is a cover and $D \subset C$. We will call the inequalities (2) “general” LCIs, and we will follow Gu *et al.* [5] in referring to the inequalities (1) as “simple” LCIs.

Example (continued). Assume as before that the knapsack constraint takes the form $4x_1 + 6x_2 + 6x_3 + 6x_4 + 6x_5 + 7x_6 + 8x_7 + 15x_8 \leq 22$. The inequality $x_1 + x_2 + x_3 + x_4 + x_5 + x_6 + 2x_7 + 3x_8 \leq 4$ can be shown to define a facet of $KP(w, c)$. It can be derived as a general LCI by setting $C = \{1, 2, 8\}$ and $D = \{8\}$.

We remark that the general LCIs with $|D| = 1$ dominate the so-called “ $(1, k)$ -configuration” inequalities of Padberg [6].

ALGORITHMIC ASPECTS

Computing Lifting Coefficients

A natural question is how to actually compute the coefficients α_j and β_j . The process of computing these coefficients is called *lifting*. One normally distinguishes between *sequential* lifting, in which the coefficients are computed one at a time, and *simultaneous* lifting, in which they are computed “all at once,” so to speak. (See **Lifting Techniques for Mixed Integer Programming** for more details on lifting.)

We will follow Gu *et al.* [5] in referring to the computation of the α_j and β_j as *up-lifting* and *down-lifting*, respectively.

The case that has received most attention is *sequential up-lifting*, which leads to simple LCIs with integral coefficients. Balas [1] and Wolsey [3] both pointed out that different lifting sequences can yield different simple LCIs. (This is how we generate the three simple LCIs with integral coefficients in the example in the section titled “Lifted Cover Inequalities.”) They also showed that, for a given lifting sequence, the up-lifting coefficients can be computed by solving a series of auxiliary 0–1 KPs.

Since solving 0–1 KPs is rather time-consuming, researchers looked for faster and simpler methods. Balas and Zemel [7] showed how to compute, in $O(n + |C| \log |C|)$

time, tight lower and upper bounds on the up-lifting coefficients, which are independent of the lifting sequence. The upper bounds were later improved by Gu *et al.* [8]. Crowder *et al.* [9] proposed to compute *approximate* up-lifting coefficients, by solving the continuous relaxation of the auxiliary 0–1 KPs, and rounding the answers down to integers. Finally, Zemel [10] pointed out that one can compute exact up-lifting coefficients for all variables in $O(n|C|)$ time, by dynamic programming.

The example given in the section titled “Lifted Cover Inequalities” shows that there exist simple LCIs with fractional coefficients, which cannot be obtained with sequential up-lifting. To derive such simple LCIs, one must perform simultaneous up-lifting. Unfortunately, this is not easy. Indeed, Hartvigsen and Zemel [11] showed that even *recognizing* simultaneously-lifted simple LCIs is $\mathcal{NP}$ -hard. On the other hand, there exist a couple of simple and fast procedures for *approximate* simultaneous up-lifting [8,12].

As for general LCIs, Gu *et al.* [5] claim that sequential lifting can be performed in $O(n^3|C|)$ time, provided that the lifting sequence satisfies a certain condition. An $O(nc)$ lifting algorithm, which imposes no conditions on the lifting sequence, is described in our article [13]. A simpler and faster alternative is to solve the continuous relaxation of the auxiliary 0–1 LPs, just as Crowder *et al.* [9] did for simple LCIs.

Separation Algorithms

In order to use a class of valid inequalities as cutting planes, one needs a *separation algorithm*, that is, a routine for generating the inequalities when they are violated (see **Branch and Cut**). Unfortunately, the separation problems for CIs, simple LCIs, and general LCIs have all been shown to be $\mathcal{NP}$ -hard [14–16], and the same seems likely to be true for ECIs. Nevertheless, some useful exact and heuristic separation algorithms are known.

We begin with CIs. Crowder *et al.* [9] noted that CI separation is equivalent to the

following knapsack-type problem:

$$\min \left\{ \sum_{j \in N} (1 - x_j^*) y_j : w^T y > c, y \in \{0, 1\}^n \right\}.$$

Here, y_j is a 0–1 variable, taking the value 1 if and only j is to be inserted into the cover C . It is not hard to show that this problem can be solved by dynamic programming in $O(nc)$ time, which is acceptable if c is not too large. Crowder *et al.* [9] suggested solving it heuristically instead, by inserting items into C in nondecreasing order of $(1 - x_j^*)/w_j$ until a cover is obtained. This heuristic takes $O(n \log n)$ time.

As for ECIs, Gabrel and Minoux [17] showed that the separation problem can be reduced to a sequence of knapsack-type problems. In our article [13], we presented a simplified version of their algorithm, which runs in $O(n^2c)$ time, along with a dynamic programming algorithm that runs in only $O(nc)$ time. We also presented an effective heuristic, that runs in $O(n^2)$ time. All of our algorithms can produce more than one violated ECI per call.

As for simple LCIs, Crowder *et al.* [9] suggested using their heuristic to obtain a CI, and then performing up-lifting to strengthen it. They pointed out that it pays to up-lift the variables with positive x^* -value first, before up-lifting the variables with zero x^* -value.

Several articles address the separation of general LCIs [4,5,13,18]. Van Roy and Wolsey [4] proposed to include only one item into D —namely, the item in C with the largest x^* -value—and leave down-lifting to the end. Hoffman and Padberg [18] proposed to set $D = \{j \in C : x_j^* = 1\}$, and then lift in the following order: up-lift the variables in $N \setminus C$ with positive x^* -value, down-lift the variables in D , then up-lift the variables in $N \setminus C$ with zero x^* -value. Gu *et al.* [5] used the same scheme, but used a different heuristic to construct C : they simply inserted items into C in nonincreasing order of x^* -value, until a cover was obtained. In our article [13], we used a similar scheme, but generated the initial covers by running our ECI heuristic.

A comparison of several different separation algorithms for CIs, ECIs, simple LCIs, and general LCIs, can be found in Ref. 13.

APPLICATIONS

Application to Combinatorial Optimization Problems

Many important combinatorial optimization problems can be relaxed, in a natural way, so that they decompose into one or more 0–1 KPs. If one solves such a problem with an LP-based solution algorithm, such as branch-and-cut, then one can use CIs, ECIs, or LCIs as cutting planes.

For the sake of brevity, we mention just a few problems to which this approach has been applied:

- the *multiple KP* [14],
- the *multidimensional KP* [13,17,19,20],
- the *generalized assignment problem* [21,22],
- the *capacitated facility location problem* [23,24],
- the *fixed-charge transportation problem* [25],
- the *capacitated network design problem* [26],
- the *prize-collecting traveling salesman problem* [27,28],
- the *orienteeing problem* [29],
- the *resource-constrained project scheduling problem* [30].

Application to General 0–1 Linear Programs

As mentioned in the introduction, valid inequalities for 0–1 knapsack polytopes can in fact be used as cutting planes for general 0–1 LPs. The idea is to consider each individual constraint of the 0–1 LP as a knapsack constraint (complementing variables if necessary to obtain nonnegative coefficients), and derive inequalities that are valid for the associated knapsack polytope. Provided the constraint matrix of the 0–1 LP is sparse, the inequalities generated in this way can be expected to be useful.

To our knowledge, Crowder *et al.* [9] were the first to test this idea computationally. They designed what is now called a *cut-and-branch* algorithm, in which cutting planes are added only at the root node of

Table 1. Percentage Gap Closed by Inequalities on MIPLIB Instances

Average	50.00	57.80	57.80	63.13	74.49

the branch-and-bound tree. The cutting planes used were simple LCIs. Hoffman and Padberg [18] extended this approach in two ways, by using full branch-and-cut (in which cutting planes can be added at any node), and using general LCIs in place of simple LCIs. Further experiments with this scheme were performed by Gu *et al.* [5].

CIs, ECIs, and LCIs turn out to be remarkably effective when applied to large, sparse 0–1 LPs. Table 1, adapted from Ref [13], shows the percentage of the integrality gap that is closed by various inequalities, when applied to twelve 0–1 LPs taken from the MIPLIB [31]. The columns labeled “sLCI” and “gLCI” correspond to simple and general LCIs, respectively. The column labeled “All” was obtained by calling an exact (and time-consuming) separation algorithm for general facets of knapsack polytopes. The CIs and ECIs were separated exactly, whereas the LCIs were separated heuristically. In all cases, apart from the “All” column, the running times were negligible compared to the time taken to solve the instances to proven optimality.

Observe that even the (theoretically weak) CIs close half of the integrality gap on average, and the other inequalities close even more. This good performance is typical, though only when the constraint matrix is sparse [13]. Observe also that the simple LCIs gave exactly the same results as the ECIs. Indeed, we observed that up-lifting

coefficients greater than 1 occurred very infrequently. This suggests that, if one does not wish to implement down-lifting, then one might as well use ECIs.

FOR FURTHER READING

There exist hard instances of the 0–1 KP that require an exponential number of nodes when solved by branch-and-bound, even if all simple LCIs are included in the LP relaxation [15,32].

LCIs are not the only facet-defining inequalities for 0–1 knapsack polytopes. For other such inequalities, see Refs 33–35.

Separation algorithms have been devised for the 0–1 knapsack polytope itself, rather than for specific classes of inequalities [13,36–38].

Cover inequalities have been derived for more complex KPs, with general integer variables, continuous variables, and so on [20,39–46].

An important related class of inequalities are the *lifted flow cover* inequalities [47–49], which are valid for fixed-charge problems.

CREDIT RISK ASSESSMENT

ARCADY NOVOSYOLOV
Institute of Mathematics, Siberian
Federal University,
Krasnoyarsk, Russia

Credit risk arises when and where any two parties go into a borrowing and lending agreement, so that one party (lender) agrees to lend another party (borrower) a fixed amount of money for a fixed period of time (till maturity). The borrower returns the lender the borrowed money according to a prespecified schedule; usually the returned amount is greater than the borrowed one, the extra payment is called *interest*, it acts as a credit price.

BOND

The simplest form of credit agreement is a bond. Zero-coupon bond represents the obligation of the bond issuer (the party that borrows money) to return the nominal of the bond to the bond holder (the party that lends money) at maturity. Usually bonds also assume regular, say annual, coupon payments, the size of which is a fixed percentage of the nominal bond value.

The price p of the bond with nominal (face) value A that expires in T years and pays annual coupon amount a starting a year from now is equal to its present value calculated with annual interest rate r in mind

$$p = f(r) = \frac{a}{1+r} + \frac{a}{(1+r)^2} + \cdots + \frac{a}{(1+r)^{T-1}} + \frac{a+A}{(1+r)^T}.$$

This formula is also used another way round: given the market price p of a bond, calculate the interest rate y such that $f(y) = p$; this interest rate y is called *yield to maturity*.

More generally, if a debt tool promises payments A_i at times $t_i, i = 1, 2, \dots, n$, then its

present value $f_t(r)$ at time $t < \min\{t_1, \dots, t_n\}$ given annual interest rate r is calculated by

$$f_t(r) = \frac{A_1}{(1+r)^{(t_1-t)}} + \cdots + \frac{A_n}{(1+r)^{(t_n-t)}} = \sum_{i=1}^n \frac{A_i}{(1+r)^{(t_i-t)}}. \quad (1)$$

To illustrate basic concepts, consider an example of a 5-year coupon bond with face value \$300 and annual coupon payment 3% or \$9. This bond generates the cash flow shown in the Table 1; weights row corresponds to Macaulay duration, see Equation (7) below.

Given the interest rate $r = 0.05$ (or 5%), the initial price of this bond is equal to

$$f_0(0.05) = \frac{9}{1.05} + \frac{9}{1.05^2} + \frac{9}{1.05^3} + \frac{9}{1.05^4} + \frac{309}{1.05^5} = \$274.02.$$

Half a year from now the price of this bond, assuming the same interest rate 5%, would raise to

$$f_{1/2}(0.05) = \frac{9}{1.05^{1/2}} + \frac{9}{1.05^{3/2}} + \frac{9}{1.05^{5/2}} + \frac{9}{1.05^{7/2}} + \frac{309}{1.05^{9/2}} = 280.79.$$

This is how the investment in bonds works. The bond value increases by \$6.77 in half a year. However, this is true only if interest rate remains unchanged. Actually, there is an interest rate risk, which means that the bond value may change if interest rate changes. Indeed, if interest rate raises to $r = 0.06$ (6%) in half a year, the new bond price becomes equal to

$$f_{1/2}(0.06) = \frac{9}{1.06^{1/2}} + \frac{9}{1.06^{3/2}} + \frac{9}{1.06^{5/2}} + \frac{9}{1.06^{7/2}} + \frac{309}{1.06^{9/2}} = \$269.84,$$

Table 1. Example Cash Flow

Year Number (i)	1	2	3	4	5
Time (t_i)	1	2	3	4	5
Payment (\$)	9	9	9	9	309
Weights [$w_{i,1/2}(0.05)$]	0.031	0.030	0.028	0.027	0.884

so that the investment in this case brings loss instead of gain, and the bond value is by \$10.95 less than expected. If, on the contrary, the interest rate falls to $r = 0.04$ (4%) in half a year, then the new bond price becomes

$$f_{1/2}(0.04) = \frac{9}{1.04^{1/2}} + \frac{9}{1.04^{3/2}} + \frac{9}{1.04^{5/2}} + \frac{9}{1.04^{7/2}} + \frac{309}{1.04^{9/2}} = \$292.32,$$

so that the investment brings gain, which is by $\$292.32 - \$280.79 = \$11.53$ greater than expected. The changing interest rate would cause deviation of future bond price from the expected one. This deviation may be quantified by derivatives of bond price function (Eq. 1). Thus, the derivatives can serve risk indicators for the bond value.

DURATION AND CONVEXITY

Minus derivative of f with respect to interest rate r is called [1] *modified dollar duration*.

$$D_t(r) = -f'_t(r) = \sum_{i=1}^n \frac{A_i(t_i - t)}{(1+r)^{t_i+1-t}}. \quad (2)$$

Modified dollar duration $D_t(r)$ indicates how large the change $\Delta f_t(r)$ of the bond price resulting from a small change Δr of interest rate would be

$$\Delta f_t(r) \approx -D_t(r)\Delta r. \quad (3)$$

In the above example, the modified dollar duration in half a year equals to

$$D_{1/2}(0.05) = \frac{9}{1.05^{1/2}} + \frac{9}{1.05^{3/2}} + \frac{9}{1.05^{5/2}} + \frac{9}{1.05^{7/2}} + \frac{309}{1.05^{9/2}} = \$1123.6,$$

thus, changing interest rate by 0.01 (1%) would cause a change in the bond value by

approximately $\$1123.6 \times 0.01 \approx \11.24 . In particular, raising the interest rate to 0.06 provides approximate price by

$$\begin{aligned} \tilde{f}_{1/2}(0.06) &= f_{1/2}(0.05) - D_{1/2}(0.05) \times 0.01 \\ &= \$280.79 - \$1123.6 \times 0.01 \\ &= \$269.55. \end{aligned} \quad (4)$$

Dividing the expression for $D_t(r)$ by bond price $f_t(r)$, we obtain *modified duration* [2]

$$B_t(r) = -\frac{f'_t(r)}{f_t(r)} = -\frac{1}{f_t(r)} \sum_{i=1}^n \frac{A_i(t_i - t)}{(1+r)^{t_i+1-t}}. \quad (5)$$

The modified duration indicates how large the relative change $\Delta f_t(r)/f_t(r)$ of the bond price resulting from a small change Δr of interest rate would be

$$\frac{\Delta f_t(r)}{f_t(r)} \approx -B_t(r)\Delta r. \quad (6)$$

In the above example, the modified duration

$$B_{1/2}(0.05) = \frac{D_{1/2}(0.05)}{f_{1/2}(0.05)} \approx 4.$$

This means that raising the interest rate by 1% would cause a drop of the bond value by about 4%. Indeed, making calculations for $t = 1/2$ and raising interest rate from 0.05 to 0.06, we get

$$\frac{f_{1/2}(0.06) - f_{1/2}(0.05)}{f_{1/2}(0.05)} = -0.039,$$

which is close to the predicted drop in value by 4%.

Multiplying $B_t(r)$ by $1+r$, we get the *Macaulay duration* (also known as *unmodified duration*, see Ref. 2)

$$M_t(r) = -(1+r) \frac{f'_t(r)}{f_t(r)} = \sum_{i=1}^n w_{it}(r)(t_i - t), \quad (7)$$

where

$$w_{it}(r) = \frac{A_i}{(1+r)^{t_i-t} f_t(r)}, \quad i = 1, \dots, n.$$

We have

$$w_1 \geq 0, \dots, w_n \geq 0; w_1 + \dots + w_n = 1,$$

so Equation (7) measures how long, on average, the investor waits before receiving a payment, which justifies the name “duration.” Weights values for the above example with $t = 1/2$ and $r = 0.05$ are presented in the last row of Table 1, and the corresponding value of the Macaulay duration is equal to $M_{1/2}(0.05) = 4.202$ years. Macaulay duration is convenient within the continuous compounding model [1].

Duration parameters provide linear approximations of the sort of Equations (3) and (6). To get better approximation, one can use quadratic approximation. Define *modified convexity* $C_t(r)$ as the second derivative of the bond price, divided by the bond price [2]

$$C_t(r) = \frac{f_t''(r)}{f_t(r)}. \quad (8)$$

Then the relative change of the bond price may be approximated by

$$\frac{\Delta f_t(r)}{f_t(r)} \approx -B_t(r)\Delta r + \frac{1}{2}C_t(r)(\Delta r)^2. \quad (9)$$

In the example of Table 1, set $t = 1/2, r = 0.05$. We have $B_{1/2}(0.05) = 4$ and $C_{1/2}(0.05) = 20.57$, so raising the interest rate to $r = 0.06$ provides the approximation

$$\begin{aligned} \tilde{f}_t(0.06) &= \$280.79 \times \left(1 - 4 \times 0.01 + \frac{1}{2} \right. \\ &\quad \left. \times 20.57 \times 0.0001 \right) = \$269.843 \end{aligned}$$

with error \$0.003, which is much better than linear approximation (Eq. 4) with error \$0.29.

DEFAULT RISK

Duration and convexity are used to measure the sensitivity of bond value to change of interest rate. These measures indicate *interest rate risk*. Another source of bond risk is the possibility of default, when a borrower cannot meet his/her obligation according to the debt contract (bond). This risk may be

described by the following two parameters: probability of default p during a period of 1 year, and recovery rate R ; the latter being the debt portion that is reimbursed to the lender, in case of default.

Some debt tools are regarded as *risk-free*, say, US government bonds. The yield to maturity of such bonds is called *risk-free interest rate* r . Risky (corporate and municipal) bonds should provide greater yield y , the difference $s = y - r$ is called *spread* of the corresponding bond, and may be regarded as price or premium for taking the risk of holding this risky bond. Let face value of a bond be A , then expected loss in case of default would be $A(1 - R)p$, and premium for risk taking is As . Assuming *risk-neutral* lender, who would require premium being equal to the expected loss, we have the equation $A(1 - R)p = As$, which gives for the *risk-neutral* probability of default

$$p = \frac{s}{1 - R}. \quad (10)$$

Consider an example. Let risk-free rate r be 3%, and a risky bond with face value A and maturity 1 year has yield to maturity 5%. This means that the spread equals 2% or 200 basis points, where basis point equals 0.0001 or 0.01%. Assuming recovery rate R to be known and equal to 50%, we get the risk-neutral default probability $p = 0.02/(1 - 0.5) = 0.04$.

Rating agencies such as S&P, Fitch, or Moody's, assign ratings to corporate debt instruments and calculate historical default probabilities for specific ratings. Examples of such ratings as well as values of corresponding default probabilities may be found at agencies sites [3–5].

Calculating default probability plays the central role in assessing default risk. The goal may be achieved using a number of models; we will consider structural models and reduced-form models.

STRUCTURAL MODELS

Structural models use information about company's equity prices, which are available for publicly traded companies. The first

model of the class belongs to Merton [6], [7, Chapter 22]. We will describe the Merton model following Ref. 7.

Suppose that a company's debt is represented by a single bond with face value D and maturity t . Denote V_0 and V_t , the values of the company's assets today and at time t , respectively, and let E_0 and E_t stand for values of equity today and at time t .

In case $V_t < D$, the company cannot make the debt repayment and should default; the equity value E_t equals 0 in this case. If, on the other hand, $V_t \geq D$, the company should repay the debt, and the equity equals $E_t = V_t - D$. In short,

$$E_t = \max(V_t - D, 0) = (V_t - D)_+, \quad (11)$$

which means that equity is a call option on assets V with strike price D and maturity t . Assuming that assets V follow a geometric Brownian motion as in Black–Scholes model [7, Chapter 13], we get the equity today value in the form

$$E_0 = V_0 N(d_1) - DE^{-rt} N(d_2), \quad (12)$$

where N stands for the standard normal cumulative distribution function,

$$d_1 = \frac{\log(V_0/D) + (r + \sigma_V^2/2)t}{\sigma_V \sqrt{t}},$$

$$d_2 = d_1 - \sigma_V \sqrt{t}, \quad (13)$$

and σ_V denotes asset volatility, which is assumed constant in this model. The risk-neutral probability of default in this model is equal to

$$p = N(-d_2). \quad (14)$$

Its calculation requires knowing the values of V_0 and σ_V , which are not directly observable in the market. However, from Ito's lemma [7], we get the equation

$$\sigma_E E_0 = N(d_1) \sigma_V V_0, \quad (15)$$

where σ_E stands for equity volatility, which may be extracted from option prices on the company stocks. Solving the two nonlinear

Equations (12) and (15), we get the values of V_0 and σ_V . Now, the probability of default is obtained by applying Equations (13) and (14).

Consider an example. Let $E_0 = 5$, $D = 10$, $\sigma_E = 0.3$, $r = 0.03$, and $t = 2$. Solving Equations (12) and (15), gives $V_0 = 14.41$ and $\sigma_V = 0.1043$. From Equation (13), we have $d_2 = 2.8121$, and, finally, $p = 0.0025$.

PRACTICAL EXAMPLE OF DEFAULT CORRELATION

Now consider a practical example of how underestimation of default correlation might cause financial instability and even a crisis. Indeed such underestimation was one of the reasons which led to the recent 2008 financial turmoil.

The chain that led to mortgage crisis is rather complicated, so we would explain the things using simpler yet similar framework of collateralized debt obligations (CDO).

Suppose a bank holds a portfolio of n bonds of different companies similar in all respects. The bonds possess the same credit quality, in particular, the same default probability p , and all have the face amount of 1 and the same maturity 1 year. For simplicity, we assume zero recovery rate. The bank wishes to transfer (a part of) the default risk to third parties in exchange for (a part of) interest rate payments. To do so, the bank creates the derivative assets called *tranches*. The number of tranches may be different, let it be three in our example, we will call them the worst, the intermediate, and the best quality tranches.

The whole system works as follows. The worst quality tranche accumulates first n_1 defaults. This means that if the actual number m of defaults till maturity does not exceed n_1 , then the holders of the intermediate and the best tranches get full repayment of their debt, while the holder of the worst tranche gets repayment for $n_1 - m$ bonds. The intermediate tranche accumulates the next n_2 defaults. This means that if the actual number of defaults m satisfies $n_1 < m \leq n_1 + n_2$, then the holder of the worst tranche gets no repayments on his/her debt, the holder of the best tranche get full repayment, and

the holder of the intermediate tranche gets repayment on $n_1 + n_2 - m$ bonds. The best tranche accumulates the rest $n_3 = n - n_1 - n_2$ defaults. This means that if the actual number m of defaults exceeds $n_1 + n_2$, then the holders of the worst and the intermediate tranches get no repayments, and the holder of the best tranche gets repayment for $m - n_1 - n_2$ bonds.

The benefit for tranches holders consists of getting interest rate payments and debt repayments conditioned according to the specified scheme. The difference of quality if reflected in the different interest rate flows for tranches. Detailed interest rate calculation is a matter of CDO pricing and is rather complicated. However, it is clear that greater default probability for a tranche should be compensated by greater interest rate payments.

In our example, we will show how wrong specification of default correlation can

dramatically change the probabilities of losses for tranches, especially for the best one. This is exactly what was going on in the mortgage-backed securities market, where tranches rated as AAA securities brought huge losses during 2008.

Now, let $n = 100, n_1 = 15; n_2 = 10, n_3 = 75$, and $p = 0.1$. Assume pairwise default correlation being the same for all pairs of bonds, and it being denoted as ρ . Denote A, B , and C events linked to the random number of defaults m , specifically: $A = \{m \leq n_1\}, B = \{n_1 < m \leq n_1 + n_2\}, C = \{n_1 + n_2 < m \leq n\}$. Monte Carlo simulation of this CDO with 10,000 trials gives the following probabilities for the events A, B, C for a number of ρ values in Table 2:

Judging by the probabilities, we can see that assuming zero correlation, we can assign the best tranche the AAA rating quality by the S&P rating system. However, if $\rho = 0.1$, its rating jumps down to B, which is outside the investment grade. Further correlation increasing moves the tranche even deeper into “junk bonds” area. Figures 1, 2 and 3 illustrate the distributions of defaults number for different values of ρ .

In a few words, the subprime mortgage crisis may be explained as follows: wrong model assessment allowed assigning too high credit rating to the best tranches, which provoked high demand from conservative investors, which gave rise to a flow of poor quality mortgages, and the whole system became a bubble.

Table 2. Probabilities of Default for Tranches

ρ	$P(A)$	$P(B)$	$P(C)$
0	0.9587	0.0413	0
0.1	0.8234	0.1495	0.0271
0.2	0.7839	0.1472	0.0689
0.3	0.7863	0.1218	0.0919
0.4	0.7788	0.1078	0.1134
0.5	0.7823	0.0848	0.1329
0.6	0.7943	0.0708	0.1349

Figure 1. Distribution of number of defaults in example when correlation $\rho = 0$.

Figure 2. Distribution of number of defaults in example when correlation $\rho = 0.2$.

Figure 3. Distribution of number of defaults in example when correlation $\rho = 0.4$.

FURTHER READING

More on duration and convexity of bonds may be found in Ref. 8 (Chapter 13). Calculation of default probability for coupon bearing bonds is illustrated by examples in Ref. 7 (Chapter 22). Empirical analysis of several structural models is presented in Ref. 9. For more practical examples of credit turmoil, the reader is referred to Ref. 10 (Chapter 1).

CREDIT RISK

TIM LEUNG
IEOR Department, Columbia
University, New York, NY USA
RONNIE SIRCAR
ORFE Department, Princeton
University, Princeton, NJ USA

INTRODUCTION

Credit derivatives are financial securities whose payouts are contingent on one or many *default events*, such as the bankruptcy of a firm, nonrepayment of a loan, or missing a mortgage payment. These instruments enormously grew in popularity in the 1990s and 2000s, and obviously declined a lot with the financial crisis of 2008. However, credit markets are still of central importance, as struggling economies enhance default risk of firms and countries. Two recent credit-linked calamities are the impact of potential default by Greece on many credit default swaps (CDSs) written by systemically large financial firms, and the \$5+ billion loss by J.P. Morgan in 2012 from large bets on the CDX credit index.

The main task is to model a random default time when a firm or obligor cannot meet a payment. This may come from a diffusion model of asset values hitting a fixed debt level, in which case we can, in some sense, see the default event coming, or it may be modeled as the jump time of some exogenous Poisson-type process (which does not have a direct economic interpretation), in which case the default comes as a surprise. Valuing multiname credit derivatives involves modeling accurately correlation of defaults across firms, and evaluating basket portfolios affected by many sources of credit risk.

STRUCTURAL MODELS

The structural approach to credit risk involves modeling the default event through

the firm's asset and debt values. For example, Merton [1] assumes that default occurs if the firm's asset value S on date T are below a prespecified debt level D . The firm's creditors hold a bond promising payment of \$1 on expiration date T , unless the firm defaults, so the bond payoff is

$$h(S_T) = \mathbf{1}_{\{S_T > D\}}.$$

Assuming that the cash flows represented by S are perfectly hedgeable (e.g., by purchasing the firm's stock) and that S is a geometric Brownian motion, we can evaluate the Black-Scholes value of the defaultable bond.

Merton Model

In the Merton [1] model, the asset value S is modeled by the geometric Brownian motion:

$$dS_t = \mu S_t dt + \sigma S_t dW_t, \quad (1)$$

where W is a Brownian motion on a probability space $(\Omega, \mathcal{F}, \mathbf{P})$. Here, $\mathbf{P}$ is the historical or subjective measure. In this case, under the unique risk-neutral pricing measure $\mathbf{P}^*$, the asset price is explicitly given by

$$S_t = S_0 \exp \left(\left(r - \frac{1}{2} \sigma^2 \right) t + \sigma W_t^* \right), \quad (2)$$

where W^* is a $\mathbf{P}^*$ -Brownian motion, and r is the short rate (assumed constant).

Assuming that default occurs if $S_T < D$ for some threshold value D , the price at time t of a defaultable bond is simply the price of an European digital option, which pays 1 if S_T exceeds the threshold and 0 otherwise. It is explicitly given by $u^d(t, S_t)$ where

$$\begin{aligned} u^d(t, S) &= \mathbf{E}^* \left\{ e^{-r(T-t)} \mathbf{1}_{\{S_T > D\}} \mid S_t = S \right\} \quad (3) \\ &= e^{-r(T-t)} \Phi(d_2), \quad (4) \end{aligned}$$

where $\mathbf{E}^*$ is the expectation under measure $\mathbf{P}^*$, and $\Phi(\cdot)$ is the normal cumulative distribution function, and

$$d_2 = \frac{\log(S/D) + (r - \frac{1}{2}\sigma^2)(T-t)}{\sigma\sqrt{T-t}}. \quad (5)$$

The formula (3) often motivates the *distance to default* definition

$$\frac{\log(S/D)}{\sigma},$$

which increases as the firm value S is far from the debt level D but decreases with increasing volatility σ .

Black–Cox Model

In the Black and Cox [2] generalization, the default time is modeled by the first time the asset value S hits a lower threshold D , namely,

$$\tau_t := \inf\{s \geq t \mid S_s \leq D\}. \quad (6)$$

Then, the value of a defaultable bond, given no default has occurred at time $t \leq T$, is given by

$$\begin{aligned} u(t, T) &= \mathbf{E}^* \left\{ e^{-r(T-t)} \mathbf{1}_{\{\tau_t > T\}} \mid S_t = S \right\} \\ &= \mathbf{E}^* \left\{ e^{-r(T-t)} \mathbf{1}_{\{\inf_{t \leq s \leq T} S_s > D\}} \mid S_t = S \right\}. \end{aligned} \quad (7)$$

If the asset price has reached D before time t , then $u(t, T) = 0$.

This defaultable zero-coupon bond is in fact a *binary down-and-out barrier option* where the barrier level and the strike price coincide. This can be computed using the distribution of the minimum of a (nonstandard) Brownian motion, obtained from the *reflection principle*, after a Girsanov change of measure. (See Ref. 3 for details of this calculation). Alternatively, the *method of images* [4] leads to a formula for $u(t, S)$ in terms of the Black–Scholes price u^d of the corresponding digital option:

$$u(t, S) = u^d(t, S) - \left(\frac{S}{D}\right)^{1-\frac{2r}{\sigma^2}} u^d\left(t, \frac{D^2}{S}\right), \quad (8)$$

where u^d is the digital pricing function given in Equation (3).

Spread Curves in the Black–Cox Model

The *yield spread* $Y(0, T)$ at time zero is defined by

$$e^{-Y(0, T)T} = \frac{P^B(0, T)}{P(0, T)}, \quad (9)$$

where $P(0, T)$ is the default-free zero-coupon bond price. Under the Black–Cox model with constant interest rate r , we have $P(0, T) = e^{-rT}$ and $P^B(0, T) = u(0, S)$ from Equation (7). This leads to the yield spread formula

$$Y(0, T) = -\frac{1}{T} \log \left(\Phi(d_2^+(T)) - \left(\frac{S}{D}\right)^{1-\frac{2r}{\sigma^2}} \Phi(d_2^-(T)) \right), \quad (10)$$

where we denote

$$d_2^\pm(T) = \frac{\pm \log\left(\frac{S}{D}\right) + \left(r - \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}}. \quad (11)$$

As discussed in Ref. 5, the challenge for theoretical pricing models is to raise the average predicted spread relative to crude models such as the constant volatility model presented in this section, without overstating the risks associated with volatility or leverage. To this end, several approaches have been proposed, including the introduction of jumps [6–8], stochastic interest rate [9], stochastic volatility [10], or imperfect information [11,12]. On the basis of a comprehensive empirical analysis, Eom *et al.* [5] find that structural models proposed in the literature [9,13] still have difficulties in predicting realistic credit spreads at short maturities.

As is well documented in the literature, in this first passage model, the likelihood of default is essentially 0 for short maturities even for highly levered firms, corresponding to S/D close to 1, as illustrated in Figure 1. In fact, for any continuous diffusion process S , the default time τ_t is a *predictable* stopping time, in the sense that it can be *announced* by an increasing sequence of stopping times. For instance, one can consider the sequence $(\tau_t^{(n)})$ defined by $\tau_t^{(n)} := \inf\{s \geq t, S_s \leq D + 1/n\}$. This feature will be one of the motivations to move to intensity-based models in which default is modeled as a surprise.

Figure 1. This figure shows the sensitivity of the yield spread to the leverage level. The volatility level is set to 10% and the interest rate is 6%. The curves increase with the decreasing ratios S/D : (1.3, 1.275, 1.25, 1.225, 1.2).

INTENSITY-BASED MODELS

The last observation serves as a motivation for intensity-based (or reduced-form) models in which default occurs at the jump of an exogenous Poisson-type process. In contrast to structural models, as the intensity-based default time is *totally inaccessible*, and cannot be predicted by any predictable stopping times [14]. The element of surprise makes intensity-based models capable of explaining nonzero credit spreads even at short maturities.

Doubly Stochastic or Cox Process

The default times are generated by a two-step randomization process described by a stochastic intensity process, λ , and Poisson process, N . We start with a probability space $(\Omega, \mathcal{G}, \mathbf{P})$ and a filtration $(\mathcal{G}_t)$. Let (H_t) be a counting process with jump times $\tau_1, \tau_2, \dots$, satisfying the nonexplosive

condition: $\lim_{n \rightarrow \infty} \tau_n = +\infty$. Then, (λ_t) is called the *intensity of H* if:

1. λ is a nonnegative predictable process;
2. $\mathbf{E}\{\int_0^t \lambda_s ds\} < \infty$ for all $t > 0$;
3. the process $M_t = H_t - \int_0^t \lambda_s ds$, $t \geq 0$, is a martingale.

Now, suppose that $(\mathcal{F}_t)$ is a subfiltration, that is, $\mathcal{F}_t \subset \mathcal{G}_t$ for all t . Then H is called a *doubly stochastic process* driven by $(\mathcal{F}_t)$ (or a $(\mathcal{F}_t)$ -conditional Poisson process, or a Poisson process conditioned by $(\mathcal{F}_t)$) if λ_t is $\mathcal{F}_t$ -predictable and, for $t > s$, conditional on $\mathcal{G}_s \vee \mathcal{F}_t$, the increment $H_t - H_s$ is Poisson distributed with parameter $\int_s^t \lambda_u du$.

In practice, the filtration $(\mathcal{F}_t)$ will be generated by some factor processes $(\mathbf{Y}_t)$ and $\lambda_t = f(\mathbf{Y}_t)$, for some (bounded nonnegative) function f . The jump times can be generated in the following way. Let $Z_0, Z_1, \dots$ be *i.i.d.* exponentially distributed random variables

with mean 1. Define $\tau_0 = 0$. Then the jump times are given by

$$\tau_n = \inf \left\{ t \geq \tau_{n-1} : \int_{\tau_{n-1}}^t \lambda_s ds \geq Z_n \right\}. \quad (12)$$

From these, we define the counting process (H_t) and the filtration $(\mathcal{H}_t)$ generated by it. Finally, the full filtration is $\mathcal{G}_t = \mathcal{F}_t \vee \mathcal{H}_t$. This construction forms the basis of a simulation method in which we successively simulate unit exponential random variables and the path of λ , while we register a jump in H according to the condition in (11).

This also reveals that, as the standard Poisson process N has unit exponential times between jumps, H can be viewed as a time-changed Poisson process. In other words, $H_t = N_{\Lambda_t}$, where $\Lambda_t = \int_0^t \lambda_s ds$.

Connection with Interest Rate Derivatives

One reason for the rapid adoption of intensity-based models is that various standard calculations central to pricing defaultable securities are similar to interest-rate derivative calculations, so that effective models in fixed income, especially those with closed-form solutions, can be adapted for credit derivatives.

To see this, consider a defaultable bond, which pays \$1 on date T as long as the Cox process H has not jumped by then. As usual, we will denote by τ this jump time:

$$\tau = \inf\{t > 0 \mid H_t > 0\}.$$

The arbitrage-free price of the defaultable bond is given by the expectation of its discounted payoff under the market-chosen risk-neutral probability $\mathbf{P}^*$, which we assume to be given. If the interest rate is zero, we have

$$\begin{aligned} \mathbf{E}^*\{\mathbf{1}_{\{\tau > T\}}\} &= \mathbf{E}^*\{\mathbf{E}^*\{\mathbf{1}_{\{\tau > T\}} \mid \mathcal{F}_T\}\} \\ &= \mathbf{E}^*\left\{e^{-\int_0^T \lambda_s ds}\right\}, \end{aligned} \quad (13)$$

where we have used the property that, conditioned on the information $\mathcal{F}_T$ (in which case, the path $(\lambda_s)_{0 \leq s \leq T}$ is given), H is an inhomogeneous Poisson process with intensity given by that path. Therefore, we reduce to computing Equation (12), which is

similar to pricing a bond with λ playing the role of a stochastic interest rate.

CIR Default Intensity

Consider a default intensity of the form $\lambda(Y_t)$, where Y is a CIR (Cox-Ingersoll-Ross or Feller or square-root) process:

$$dY_t = a(\bar{y} - Y_t)dt + \sigma\sqrt{Y_t}dW_t^*. \quad (14)$$

This is a mean-reverting process (with long-run mean-level $\bar{y} > 0$) that stays positive with probability 1 as long as $\sigma^2 < 2a\bar{y}$. It was introduced as a model of short rates in Ref. 15. Properties of this process, including the aforementioned condition for it to stay positive, were studied by Feller [16].

To compute the conditional default probability $u(t, y) = \mathbf{P}^*\{\tau > T \mid Y_t = y\}$, we look for a solution that is exponentially affine in y :

$$u(t, y) = A(T - t)e^{-B(T-t)y},$$

for functions A and B to be determined. Substituting this *ansatz* into the PDE and comparing terms with and without y , we obtain two ODEs for A and B with the initial conditions $A(0) = 1$ and $B(0) = 0$. The ODEs can be solved explicitly (see Chapter 7, [17]), yielding

$$\begin{aligned} A(s) &= \left(\frac{2\theta e^{(\theta+a)s/2}}{(\theta+a)(e^{\theta s} - 1) + 2\theta} \right)^{2a\bar{y}/\sigma^2} \\ B(s) &= \frac{2(e^{\theta s} - 1)}{(\theta+a)(e^{\theta s} - 1) + 2\theta} \\ \theta &= \sqrt{a^2 + 2\sigma^2}. \end{aligned} \quad (15)$$

The yield spread (for constant short rate) is given by

$$\begin{aligned} Y_{\text{sp}}(0, T) &= -\frac{1}{T} \log u(0, y) \\ &= -\frac{1}{T} (\log A(T) - B(T)y). \end{aligned}$$

It is easy to show that

$$\begin{aligned} B(T) &\sim \frac{2}{\theta + a}, \quad \text{and} \\ A(T) &\sim \left(\frac{2\theta}{\theta + 1} e^{(a-\theta)T/2} \right)^{2a\bar{y}/\sigma^2}, \end{aligned}$$

as $T \rightarrow \infty$. Therefore, the long-term spread converges to a positive constant:

$$Y_{\text{sp}}(0, T) \rightarrow \frac{a\bar{y}}{\sigma^2}(\theta - a) = \frac{a\bar{y}}{\sigma^2}(\sqrt{a^2 + 2\sigma^2} - a).$$

Similarly, in the short maturity limit, as $T \downarrow 0$, we have $Y_{\text{sp}}(0, T) \rightarrow y > 0$.

Credit Default Swaps

A CDS contract is a derivative that provides insurance against the default of a reference entity, which is usually a corporation or a sovereign (i.e., a national government). In a single-name CDS, the *protection buyer*, that is, the counterparty that receives a payoff if the reference entity defaults, pays a periodic premium to the *protection seller*. In return, the protection seller has to compensate the protection buyer in the case where the reference entity defaults before a predetermined maturity time. The premiums that the protection buyer pays to the protection seller are usually paid quarterly or semiannually until the maturity of the CDS contract, or until the time of the default event, whichever comes first. CDSs are among the most liquid single-name credit derivatives and provide a good indication of the market's view toward the credit risk of the underlying firm.

To fix ideas, suppose that the CDS is written on a bond issued by the reference entity. In the case where the reference entity defaults before the maturity of the CDS contract, we assume that the protection seller compensates the protection buyer with a cash settlement. In particular, the protection seller will make a cash payment to the protection buyer equal to the difference of the notional amount of the bond and its postdefault market value, which is usually determined by polling several dealers. Here, we assume that in default the bond recovers $1 - q$ of its face value—which is known as *recovery of face value*—and the protection seller provides the remaining proportion q of the face value to the protection buyer.

While there are other types of settlement used in practice, we will not go into details here. For a detailed specification on the repayment methods at default, more

information on what constitutes a default event, usual practices for settlements in the financial industry, and other legal issues we refer to Chapter 8 [18].

The pricing of a CDS amounts to determining the *CDS spread*, which determines the amount paid by the protection buyer to the protection seller on each payment date. Note that the CDS is *unfunded* in the sense that entering into the contract, as the protection seller does not require depositing the potential insurance payments upfront: an investor can receive the premium (insurance premium) without having to tie up the possible insurance payout. As a result, they have been popular with hedge funds in that they provide access to returns from high yields for bearing credit risk but with little capital constraints.

MULTINAME CREDIT DERIVATIVES

Multiname derivatives, especially collateralized debt obligations (CDOs), have played a significant role in the 2008 financial crisis. It is a major challenge in credit risk to value exotic credit derivatives, whose payoffs are contingent on defaults of many (sometimes hundreds) different firms. These defaults are certainly not independent, as firms may be linked through contracts and transactions and share common macroeconomic conditions.

Collateralized Debt Obligations (CDOs)

CDOs have been attractive because of the high yields they offer relative to poorly performing stocks and bonds in recent years. They also allow certain pension funds, mutual funds, and endowments, which are prohibited from investing directly in lower-rated debt, to acquire higher yields from CDO tranches, which are typically given higher credit ratings than some of the components. See Refs 19–21 for a concise introduction.

A CDO has two parties, the protection buyer and the protection seller (the tranche holder). The former pays to the latter a yield or tranche spread (the insurance premium) on the remaining amount that the protection

seller is still responsible for. As losses reach his tranche, the protection provider pays those claims to the protection buyer.

As an example, the CDX index is an average yield spread for a standardized basket of 125 US investment grade firms. In a CDO on the CDX index, each firm has the same notional, \$80,000, meaning the default of each firm results in a loss of at most \$80,000, but usually less because there is some recovery, to be covered by the tranche holder. The total notional is then $\$80,000 \times 125 = \10 million. Its equity tranche covers the first 3% of losses, the first mezzanine tranche the next 4%, the second mezzanine tranche the next 3%, the third mezzanine the next 5%, and the senior tranche the next 15%. These reward the tranche holder with yields such as 1500, 400, 100, 50, 15 basis points on their remaining notional.

In general, the number of firms underlying the CDO is denoted by N and the total notional by M . Each tranche is characterized by its lower and upper attachment points, denoted K_L and K_U , respectively. For example, for CDOs on the CDX, we have

Tranche	K_L	K_U
Equity	0%	3%
Mezzanine 1	3%	7%
Mezzanine 2	7%	10%
Mezzanine 3	10%	15%
Senior	15%	30%

The corresponding standardized index portfolio for European firms is called the *iTraxx*, and CDOs on that have slightly different attachment points.

The focus of modeling in the credit derivatives industry has been on *correlation* between default times. This is partly due to the industry's early adoption of the one-factor Gaussian copula model as industry standard and the practice (up till recently) of analyzing through implied correlation. This revealed that traded prices of senior tranches could only be realized through these

models with an implausibly high correlation parameter, the so-called *correlation smile*. After the simultaneous downgrades of Ford and General Motors in May 2005, the standard copula model often could not fit the data.

Multiname Intensity Models

The pricing of multiname credit derivatives requires (i) realistic modeling of the firms' default times and the correlation between them and (ii) efficient computational methods for computing the portfolio loss distribution. Dynamic factor models, a widely used class of pricing models in the literature, can be computationally tractable despite the large dimension of the pricing problem, thus satisfying issue (ii), but to have any hope of calibrating market data, such as CDO spreads, numerically intense versions of these models have to be implemented.

The most widely used framework for single-name default modeling is the intensity-based setup, in which the arrival of default of a firm is described by the first jump of a *Cox process* (or doubly stochastic Poisson process). Extensions of this dynamic framework to multiname credit derivatives were proposed by Duffie and Gârleanu [22], and more recently by Mortensen [23] in the class of common factor models.

These are part of the *bottom-up* framework of multiname credit derivatives pricing models, as the distribution of cumulative loss is modeled through the individual firms' default times and losses. Within this framework, a popular approach is to assume that a firm's probability of default depends on two components: firm-specific (or idiosyncratic), and market-wide (or systematic). In addition, the conditional default events of any two firms in the portfolio, given the systematic factors, are independent. This class of factor models has been used for at least a decade, with the technical reports [24–26], where the notions of systematic and idiosyncratic credit risks were introduced.

Suppose there are N firms whose default times are τ_i , $i = 1, \dots, N$. We also have a fixed finite time horizon T (the maturity of the CDO), and assume a constant recovery rate $\delta \in [0, 1)$. Each default time is the first

jump of a Cox process with intensity process $(\lambda_t^{(i)})$, which is decomposed into the common factor way as

$$\lambda_t^{(i)} = X_t^{(i)} + a_i Y_t$$

Here, the a_i are nonnegative constants and the $X^{(i)}$ and Y are independent *affine jump diffusions* (AJD) suitably restricted to remain positive, so that the intensity remains positive. They are defined through the SDEs [27]:

$$\begin{aligned} dX_t^{(i)} &= \kappa_i(\theta_i - X_t^{(i)})dt + \sigma_i\sqrt{X_t^{(i)}}dW_t^{(i)} \\ &\quad + dJ_t^{(i)} \end{aligned} \quad (16)$$

$$\begin{aligned} dY_t &= \kappa_Y(\theta_Y - Y_t)dt + \sigma_Y\sqrt{Y_t}dW_t^{(Y)} \\ &\quad + dJ_t^{(Y)}, \end{aligned} \quad (17)$$

where the processes $(W^{(Y)}, W^{(1)}, \dots, W^{(N)})$ are independent Brownian motions and $(J^{(Y)}, J^{(1)}, \dots, J^{(N)})$ are independent pure jump processes with constant intensities $(\ell_Y, \ell_1, \dots, \ell_N)$ and jump sizes independent of the jump times that are exponentially distributed with means $(\mu_Y, \mu_1, \dots, \mu_N)$.

This is written in the shorthand

$$X^{(i)} \sim \text{AJD}(X_0^{(i)}, \kappa_i, \theta_i, \sigma_i, \ell_i, \mu_i), \quad (18)$$

$$Y \sim \text{AJD}(Y_0, \kappa_Y, \theta_Y, \sigma_Y, \ell_Y, \mu_Y). \quad (19)$$

We assume the usual restrictions: $\sigma_i^2 \leq 2\kappa_i\theta_i$ and $\sigma_Y^2 \leq 2\kappa_Y\theta_Y$. According to (16)–(17), along with the coefficients a_i , the total number of parameters in the model is $6 + 7N$, which is on the order of 800 for a standard CDO of 125 firms. Obviously to calibrate five or six tranche spreads at three or four different maturities, there is a massive over-specification problem.

Mortensen [23] discusses calibration, but with a very reduced form of the model, with a lot of homogeneous parameters. Of course, this is necessary because of the overfitting problem discussed previously. Similar reduction is assumed in Ref. 27. A more thorough test of this type of full bottom-up model is clearly needed, and perhaps the model should be reduced in a more data-driven manner than with an ad hoc selection [28].

Top-Down Models

While bottom-up models have the good feature of allowing for consistency with single-name yield spreads, but they can be computationally intractable when computing CDO spreads unless constructed in a fairly specific manner. In addition, they may be considered better than static copula models, but may have too many parameters to fit a few tranches and maturities. In contrast, the computational problem is trivialized if we pass on to top-down models in which the loss process is modeled directly. The trade-offs of the top-down approach are as follows:

1. No consistency with the constituent single-name spreads. The “down” in top-down is essentially redundant, as we do not know how to go from the macroscopic description of the loss process L_t down to each single-name default timing and loss distribution.
2. No direct way to create individual loss processes consistently for different but overlapping baskets consistent. One can potentially model the loss process for *all* firms associated with all contracts in question, but the difficulty lies in projecting to overlapping subsets for different multiname contracts.

On the other hand, the top-down approach is used all the time when we price S&P 500 index options by modeling the S&P 500 index directly, without worrying about its relation to the component stocks. One of the motivation practitioners has promoting top-down models, as effective descriptors of (at least index) CDO tranche spreads is to encourage a derivative market in options on tranches.

The top-down approach is relatively recent in credit risk. A starting point is [29], which discusses strategies for trying go “down” to single names. Models based on self-exciting Hawkes processes are proposed and analyzed in Ref. 30. Models based on Markov chains are proposed in Refs 31 and 32. An approach related to the HJM framework for interest-rate derivatives is proposed in Refs 33 and 34; see Ref. 35 for details.

Self-Affecting Models

There is a strong case made in Ref. 30, which default events cause credit spreads to rise across the board, and so jumps in the loss process should directly affect the distribution of the next default time, for example, by directly causing a spike in the intensity of the loss process. The bottom-up approach we studied previously had no such “event feedback,” as it was based on doubly stochastic default times. People argue that without event feedback, bottom-up models need “too much” correlation to accurately capture tranche spreads, though of course “too much” is a highly subjective issue.

A simple static model containing event feedback was proposed in Ref. 19. Let Z_i denote the indicator random variable of the i th firm: $Z_i = \mathbf{1}_{\{\tau_i \leq t\}}$, which is clearly a Bernoulli variable with 1 signifying default. The Z_i are given by

$$Z_i = X_i + (1 - X_i) \left(1 - \prod_{j \neq i} (1 - X_j Y_{ji}) \right),$$

where the X_i and Y_{ji} are independent Bernoulli random variables with success probabilities p and q , respectively. The X_i can be thought of as firm i ’s intrinsic default indicator. Alternatively, firm i may default because another firm j defaults and its connection Y_{ji} to it kicks in too. Thus it is “infected” by firm j . The pictures in the Davis-Lo paper show the range of loss distributions that can be achieved with this simple two-parameter family of models, so the infection mechanism is quite powerful.

In the Hawkes process model of Errais *et al.* [30], the default counting process (N_t) admits a stochastic intensity of the form:

$$d\lambda_t = \kappa(\lambda_\infty - \lambda_t) dt + \delta dN_t,$$

so each jump in N induces a jump of size δ in λ . Note however, owing to the macroscopic blurring of identity, any default causes a jump in λ , no matter how insignificant or unconnected that firm is to other members of the portfolio.

Arnsdorff and Halperin [31] argue that the intensity of the loss process should decrease, as the number of defaults increases, because there are less firms left. In other words, an imminent default is more likely when there are more firms in the basket. Hence, they propose an intensity process of the form

$$\lambda_t = f_{N_t}(t)(n - N_t),$$

where n is the total number of firms in the pool and the f_j are deterministic versions of time (to be calibrated). A more general model incorporating level-dependent intensity, Brownian fluctuations, self-excitation is

$$\lambda_t = F(t, N_t)Y_t,$$

where $F(t, j)$ is decreasing in j and the stochastic factor Y follows a jump-diffusion:

$$dY_t = (\dots) dt + (\dots) dW_t + (\dots) dN_t.$$

Lopatin and Misirpashaev [32] proposed a model the intensity

$$d\lambda_t = \kappa(\rho(t, L_t) - \lambda_t) dt + \sigma \sqrt{\lambda_t} dW_t,$$

where $\rho(t, L)$, a function of time and loss, is to be calibrated. This idea is analogous to volatility surface estimation (Dupire’s method, etc.) in equity derivatives.

FURTHER ISSUES IN CREDIT RISK

One recent development in credit risk focuses on modeling counterparty risk and the evaluation of credit valuation adjustment (CVA). This is highlighted in the recent financial crisis, where two-thirds of losses were attributed to CVA losses from counterparty risk, while only one-third were due to actual defaults of the underlying entities. This also raised the related issue of wrong way risk, whereby the underlying contract and the default of the counterparty are correlated in the worst possible way for the investor. The Basel Committee on Banking Supervision (BCBS) has proposed a new regulatory framework—Basel III—to increase bank capital requirements for counterparty credit

risk. Recent studies on counterparty risk for CDS and other derivatives include Refs 36 and 37.

An alternative to the standard risk-neutral pricing mechanism is the utility-based approach that incorporates market frictions, such as hedging constraints, as well as the investor's risk preferences. This methodology has been recently applied to manage credit risk for single-name and multiname credit portfolios; see Refs 38–40.

Credit risk has very far-reaching impacts on the financial market, not only within the United States but also around the globe. After the 2008 financial crisis, credit risk has become a crucial part of *systemic risk* and has motivated a host of recent research. For a collection of recent works and details on the subject, we refer to Ref. 41.

CROATIAN OPERATIONAL RESEARCH SOCIETY

ZORAN BABIĆ
University of Split, Faculty of
Economics, Split, Croatia

LUKA NERALIĆ
University of Zagreb, Faculty of
Economics and Business, Zagreb,
Croatia

The war against Croatia, which started in 1991, helped the formation of the national OR society of Croatia. Also, organization of the First OR Conference KOI '91 in December 1991 was important in establishing the Croatian Operational Research Society (CRORS). Two groups of OR people, one from Zagreb (Lj. Martić, V. Čerić, M. Mauher, L. Neralić, I. Gjenero, T. Vujković, I. Jemrić, V. Bahovec, Ž. Požgaj, B. Šego, V. Vojvodić-Rosenzweig, D. Kalpić, and others) and the other from Split (Z. Babić and his group), were active in organizing the conference and establishing CRORS, together with colleagues from Varaždin (T. Hunjak and others,) and Rijeka (M. Marinović and others). Some of the Croatian OR people from abroad (S. Zlobec, J. Skorin-Kapov, D. Skorin-Kapov, and others) and colleagues from Slovenia (S. Indihar, L. Zadnik Stirn, M. Bastič, V. Rupnik, L. Arih, and others) also lent their support in establishing CRORS.

In September 1991 a group of OR people from Croatia, because of the war against Croatia, decided not to take part in the Yugoslav Symposium SYM-OP-IS '91 on OR and to withdraw the papers submitted for presentation at the symposium. After that, due to the initiative taken by the colleagues from Split, the OR people from the Faculty of Economics, University of Zagreb, started to organize the First OR Conference KOI '91 in Zagreb. Members of the program committee were V. Čerić, I. Gjenero, Lj. Martić, L. Neralić, and T. Vujković, and members of the organizing committee were

I. Jemrić, V. Bahovec, Ž. Požgaj, B. Šego, and V. Vojvodić-Rosenzweig. In this manner, OR people from Croatia and Slovenia were given the opportunity to present their papers and recent research results. At the end of October 1991, a call for papers was sent and the First OR Conference KOI '91 was held on December 21, 1991 at the Faculty of Economics, Zagreb. There were more than 60 participants at the conference. They were from Zagreb, Split, Rijeka, Varaždin, Ljubljana, and Maribor. In the proceedings of the conference, edited by Lj. Martić and L. Neralić, 28 scientific OR papers were published. A round table was organized at the conference and one of the conclusions was that the OR Society of Croatia should be established. On March 21, 1992 CRORS was established at the meeting held at the Faculty of Economics Zagreb. There were about 60 participants: mathematicians, economists and engineers from Croatia. At the meeting they accepted the documents necessary for the formation of the society and an executive committee was elected. The first president was L. Neralić, vice president V. Vojvodić-Rosenzweig, secretary K. Šorić, and treasurer I. Jemrić.

The formation of the CRORS was primarily an academia-led initiative. Later, some people from industry and other sectors joined the Society.

In the early years, one of the activities was organizing lectures on theoretical and applied OR topics for members of CRORS and members of the Seminary for Mathematical Programming and Game Theory at the Department of Mathematics, University of Zagreb. The other activity was organizing the national OR conferences, which were also open to participants from abroad, every year. In this manner the second (1992), third (1993), fourth (1994), and fifth (1995) OR conferences were organized. In 1996, the Sixth International OR Conference was organized. At that conference it was agreed with the Slovenian OR group, which was

co-organizer of OR Symposiums every year, that international meetings will be organized every two years.

In 1994, CRORS became the 43rd member of IFORS and a member of EURO.

In 1996 in Prague, at the meeting of representatives of the Austrian, Croatian, Czech, and Slovak OR Societies, it was accepted that CRORS joins these societies (including the Hungarian OR Society) in editing the Central European Journal for Operations Research and Economics (CEJORE). Later the journal was named the Central European Journal for Operations Research (CEJOR) and up to now, CRORS supports it as one of the publishing societies.

In April 24–26 1997, CRORS organized the 20th meeting of the EURO Working Group on Financial Modeling at the Interuniversity Center in Dubrovnik, Croatia, with about 50 participants. The organizers of the meeting were L. Neralić, M. Mauher, J. Skorin-Kapov, D. Skorin-Kapov, and Z. Sikora with the help of Jaap Spronk.

The Sixth International Conference on Parametric Optimization and Related Topics PARAOPT VI was organized by CRORS at the Hotel Excelsior in Dubrovnik, Croatia, in October 4–8, 1999. The main organizers of the conference were J. Guddat, H. Th. Jongen, R. Hirabayashi, S. Zlobec, and L. Neralić (Chairman of the Organizing Committee). There were more than 60 participants from Europe, United States, and Canada. Among them there was a group of graduate students from Croatia. The invited speakers for plenary lectures were H. Maurer, B. Mordukovich, P. Kall, A. P. Wierbicky, and L. M. Seiford. For the tutorial lectures the invited speakers were S. Zlobec, J. Guddat, H. Th. Jongen, R. E. Wendell, H. Peters, M. Kress, and J. Dupačova. Some presented papers were published in the special issue of the journal "Optimization" (Vol. 49, No.4, 2001) with guest editors J. Guddat, H. Th. Jongen, L. Neralić, and S. Zlobec.

CRORS organized the 21st Conference on the European Chapter on Combinatorial Optimization ECCO XXI at the Faculty of Economics in Dubrovnik, Croatia (May 29–31, 2008). At the conference there were more than 100

registered participants from all over the world. The members of the scientific committee were V. Boljunčić (co-chair), J. Skorin-Kapov (co-chair), S. Martello, J. Blazewicz, Van-Dat Cung, A. Hertz, L. Neralić, D. Skorin-Kapov, and P. Thoth, and the members of the organizing committee were K. Šorić (Chair), R. Manger, and V. Boljunčić. Plenary speakers were S. Martello, C. Roucairol, M. Laguna, D. Skorin-Kapov, A. Levin, and J. Edmonds.

Now there are about a hundred active members in CRORS who are mainly professors and assistants from the Croatian faculties, and most of them belong to the department of economics. Most of them are mathematicians by their formal education, but there are also a number of people who are economists or engineers. There are still not many active members from industry, banking, insurance, and other sectors: this seems to be a problem that is not easy to solve, but steps will be taken to change this. Nowadays the Faculty of Economics at Zagreb does not have the two year Master's degree study in OR as it used to. According to the Bologna agreement on education, there is a one-year postgraduate program on "OR and Optimization" for university specialists in OR and optimization. In the last two years, there were not enough students interested in it but in the academic year 2009/2010 the first group of six students started this study. There is no Ph.D. study in OR in Croatia and it is not known when and how it will be established. CRORS expects to get support from the Ministry of Science, Education, and Sport of the Republic of Croatia to continue to be among the OR societies that contribute to publishing CEJOR.

The first president of CRORS, as stated before, was Professor Luka Neralić from the Faculty of Economics and Business, Zagreb. After him, the president was Professor Hunjak from the Faculty of Organization and Informatics, Varaždin, who was succeeded by Professor Kristina Šorić again from the Faculty of Economics and Business, Zagreb. The last two presidents were from the coastal part of the country. The first of the two was Professor Valter Boljunčić from the youngest Croatian university, Juraj Dobrila University

of Pula, from the Department of Economics and Tourism “Dr. Mijo Mirković.” Now the president is again from a town located on the

Adriatic coast: Professor Zoran Babić from the Faculty of Economics in Split.

CROSS-ENTROPY METHOD

DIRK P. KROESE
School of Mathematics and
Physics, The University of
Queensland, Brisbane,
Australia

The *cross-entropy (CE) method* is a recent generic Monte Carlo technique for solving complicated simulation and optimization problems. The approach was introduced by Rubinstein in [1,2], extending his earlier work on variance minimization methods for rare-event probability estimation [3].

The CE method can be applied to two types of problems:

1. *Estimation.* Estimate $\ell = \mathbb{E}[H(\mathbf{X})]$, where $\mathbf{X}$ is a random variable or vector taking values in some set $\mathcal{X}$ and H is function on $\mathcal{X}$. An important special case is the estimation of a probability $\ell = \mathbb{P}(S(\mathbf{X}) \geq \gamma)$, where S is another function on $\mathcal{X}$.
2. *Optimization.* Optimize (i.e., maximize or minimize) $S(\mathbf{x})$ over all $\mathbf{x} \in \mathcal{X}$, where S is some objective function on $\mathcal{X}$. S can be either a known or a *noisy* function. In the latter case, the objective function needs to be estimated, for example, via simulation.

In the estimation setting, the CE method can be viewed as an adaptive *importance sampling* procedure that uses the *CE or Kullback–Leibler divergence* as a measure of closeness between two sampling distributions. In the optimization setting, the optimization problem is first translated into a rare-event estimation problem, and then the CE method for estimation is used as an adaptive algorithm to locate the optimum.

An easy tutorial on the CE method is given in [4]. A more comprehensive treatment can be found in [5]; see also [6], Chapter 8. The CE method homepage can be found at www.cemethod.org.

The CE method has been successfully applied to a diverse range of estimation and optimization problems, including buffer allocation [7], queueing models of telecommunication systems [8,9], optimal control of HIV/AIDS spread [10,11], signal detection [12], combinatorial auctions [13], DNA sequence alignment [14,15], scheduling and vehicle routing [16–21], neural and reinforcement learning [22–26], project management [27], rare-event simulation with light- and heavy-tail distributions [28–31], and clustering analysis [32–34]. Applications to classical combinatorial optimization problems including the max-cut, traveling salesman, and Hamiltonian cycle problems are given in [3] and [35–37]. Various CE estimation and noisy optimization problems for reliability systems and network design can be found in [38–45]. Parallel implementations of the CE method are discussed in [46] and [47], and recent generalizations and advances are explored in [48].

THE CROSS-ENTROPY METHOD FOR ESTIMATION

Consider the estimation of

$$\ell = \mathbb{E}_f H(\mathbf{X}) = \int H(\mathbf{x}) f(\mathbf{x}) d\mathbf{x}, \quad (1)$$

where H is the *sample performance function* and f is the probability density of the random variable (vector) $\mathbf{X}$. (For notational convenience it is assumed that $\mathbf{X}$ is a continuous random variable; if $\mathbf{X}$ is a discrete random variable, simply replace the integral in (1) by a sum.) Let g be another probability density such that for all $\mathbf{x}$, $g(\mathbf{x}) = 0$ implies that $H(\mathbf{x})f(\mathbf{x}) = 0$. Using the probability density g , we can represent ℓ as

$$\ell = \int H(\mathbf{x}) \frac{f(\mathbf{x})}{g(\mathbf{x})} g(\mathbf{x}) d\mathbf{x} = \mathbb{E}_g \left[H(\mathbf{X}) \frac{f(\mathbf{X})}{g(\mathbf{X})} \right]. \quad (2)$$

Consequently, if $\mathbf{X}_1, \dots, \mathbf{X}_N$ are independent random vectors, each with probability density g , then

$$\hat{\ell} = \frac{1}{N} \sum_{k=1}^N H(\mathbf{X}_k) \frac{f(\mathbf{X}_k)}{g(\mathbf{X}_k)} \quad (3)$$

is an unbiased estimator of ℓ . Such an estimator is called an *importance sampling estimator*. The optimal importance sampling probability density is given by $g^*(\mathbf{x}) \propto |H(\mathbf{x})|f(\mathbf{x})$ [6, p. 132], which in general is difficult to obtain. The idea of the CE method is to choose the importance sampling density g in a specified class of densities such that the *CE* or *Kullback–Leibler divergence* between the optimal importance sampling density g^* and g is minimal. The Kullback–Leibler divergence between two probability densities g and h is given by

$$\begin{aligned} \mathcal{D}(g, h) &= \mathbb{E}_g \left[\ln \frac{g(\mathbf{X})}{h(\mathbf{X})} \right] = \int g(\mathbf{x}) \ln \frac{g(\mathbf{x})}{h(\mathbf{x})} d\mathbf{x} \\ &= \int g(\mathbf{x}) \ln g(\mathbf{x}) d\mathbf{x} - \int g(\mathbf{x}) \ln h(\mathbf{x}) d\mathbf{x}. \end{aligned} \quad (4)$$

In most cases of interest, the sample performance function H is nonnegative, and the “nominal” probability density f is parameterized by a finite-dimensional vector $\mathbf{u}$; that is, $f(\mathbf{x}) = f(\mathbf{x}; \mathbf{u})$. It is then customary to choose the importance sampling probability density g in the *same* family of probability densities; thus, $g(\mathbf{x}) = f(\mathbf{x}; \mathbf{v})$ for some *reference parameter* $\mathbf{v}$. The CE minimization procedure then reduces to finding an optimal reference parameter vector, $\mathbf{v}^*$. This $\mathbf{v}^*$ turns out to be the solution to the maximization problem $\max_{\mathbf{v}} \int H(\mathbf{x}) f(\mathbf{x}; \mathbf{u}) \ln f(\mathbf{x}; \mathbf{v}) d\mathbf{x}$, which in turn can be estimated via simulation by solving with respect to $\mathbf{v}$, the stochastic counterpart program

$$\max_{\mathbf{v}} \frac{1}{N} \sum_{k=1}^N H(\mathbf{X}_k) \frac{f(\mathbf{X}_k; \mathbf{u})}{f(\mathbf{X}_k; \mathbf{v})} \ln f(\mathbf{X}_k; \mathbf{v}), \quad (5)$$

where $\mathbf{X}_1, \dots, \mathbf{X}_N$ is a random sample from $f(\cdot; \mathbf{w})$, for any reference parameter $\mathbf{w}$. The maximization (5) can often be solved *analytically*, in particular, when the class of

sampling distributions forms an *exponential family* [6, pp. 319–320]. Indeed, analytical updating formulas can be found whenever explicit expressions for the *maximal likelihood estimators* of the parameters can be found [4, p. 36].

Often $\ell = \mathbb{P}(S(\mathbf{X}) \geq \gamma)$, for some performance function S and level γ , in which case $H(\mathbf{x})$ takes the form of an *indicator function*: $H(\mathbf{x}) = I_{\{S(\mathbf{x}) \geq \gamma\}}$; that is, $H(\mathbf{x}) = 1$ if $S(\mathbf{x}) \geq \gamma$, and 0 otherwise. A complication in solving (Eq. 5) occurs when ℓ is a *rare-event probability*; that is, a very small probability (say less than 10^{-5}). Then, for moderate sample size N most or all of the values $H(\mathbf{X}_k)$ in (5) are zero, and the maximization problem becomes useless. In that case a *multilevel* CE procedure is used, where a sequence of reference parameters and levels is constructed with the goal that the first converges to $\mathbf{v}^*$ and the second to γ . This leads to the following algorithm [6, p. 238].

Algorithm 1 [CE Algorithm for Rare-Event Estimation].

1. Define $\hat{\mathbf{v}}_0 = \mathbf{u}$. Let $N^e = \lceil \rho N \rceil$. Set $t = 1$ (iteration counter).
2. Generate a random sample $\mathbf{X}_1, \dots, \mathbf{X}_N$ according to the probability density $f(\cdot; \hat{\mathbf{v}}_{t-1})$. Calculate the performances $S(\mathbf{X}_i)$ for all i , and order them from smallest to largest, $S_{(1)} \leq \dots \leq S_{(N)}$. Let $\hat{\gamma}_t$ be the sample $(1 - \rho)$ -quantile of performances; that is, $\hat{\gamma}_t = S_{(N - N^e + 1)}$. If $\hat{\gamma}_t > \gamma$, reset $\hat{\gamma}_t$ to γ .
3. Use the **same** sample $\mathbf{X}_1, \dots, \mathbf{X}_N$ to solve the stochastic program (5), with $\mathbf{w} = \hat{\mathbf{v}}_{t-1}$. Denote the solution by $\hat{\mathbf{v}}_t$.
4. If $\hat{\gamma}_t < \gamma$, set $t = t + 1$ and reiterate from Step 2; otherwise, proceed with Step 5.
5. Let T be the final iteration counter. Generate a sample $\mathbf{X}_1, \dots, \mathbf{X}_{N_1}$ according to the probability density $f(\cdot; \hat{\mathbf{v}}_T)$ and estimate ℓ via importance sampling, as in (3).

Apart from specifying the family of sampling probability densities, the initial vector $\hat{\mathbf{v}}_0$, the sample size N , and the rarity

parameter ρ (typically between 0.01 and 0.1), the algorithm is completely self-tuning. The sample size N for determining a good reference parameter can usually be chosen to be much smaller than the sample size N_1 for the final importance sampling estimation, say $N = 1000$ versus $N_1 = 100,000$. Under certain technical conditions, the deterministic version of Algorithm 1 is guaranteed to terminate (reach level γ) provided that ρ is chosen small enough [5, Section 3.5].

THE CROSS-ENTROPY METHOD FOR OPTIMIZATION

Let $\mathcal{X}$ be an arbitrary set of *states* and let S be a real-valued performance function on $\mathcal{X}$. Suppose we wish to find the maximum of S over $\mathcal{X}$, and the corresponding state $\mathbf{x}^*$ at which this maximum is attained (assuming for simplicity that there is only one such state). Denote the maximum by γ^* , we thus have

$$S(\mathbf{x}^*) = \gamma^* = \max_{\mathbf{x} \in \mathcal{X}} S(\mathbf{x}). \quad (6)$$

This setting includes many types of optimization problems: discrete (combinatorial), continuous, mixed, and constrained problems. Moreover, if one is interested in minimizing rather than maximizing S , one can simply maximize $-S$.

Now associate with the above problem, the estimation of the probability $\ell = \mathbb{P}(S(\mathbf{X}) \geq \gamma)$, where $\mathbf{X}$ has some probability density $f(\mathbf{x}; \mathbf{u})$ on $\mathcal{X}$ (e.g., corresponding to the uniform distribution on $\mathcal{X}$) and γ is some level. If γ is chosen close to the unknown γ^* , then ℓ is, typically, a rare-event probability, and the CE approach of the previous section can be used to find an importance sampling distribution close to the theoretically optimal importance sampling density, which concentrates all its mass on the point $\mathbf{x}^*$. Sampling from such a distribution thus produces optimal or near-optimal states. A main difference with the CE method for rare-event simulation is that in the optimization setting the final level $\gamma = \gamma^*$ is not known in advance. The CE method for optimization produces a sequence of levels $\{\hat{\gamma}_t\}$ and reference parameters $\{\hat{\mathbf{v}}_t\}$ such that

the former tends to the optimal γ^* and the latter to the optimal reference vector $\mathbf{v}^*$ corresponding to the point mass at $\mathbf{x}^*$ [6, p. 251].

Algorithm 2 [CE Algorithm for Optimization].

1. Choose an initial parameter vector $\hat{\mathbf{v}}_0$. Let $N^e = \lceil \rho N \rceil$. Set $t = 1$ (level counter).
2. Generate a sample $\mathbf{X}_1, \dots, \mathbf{X}_N$ from the probability density $f(\cdot; \hat{\mathbf{v}}_{t-1})$. Calculate the performances $S(\mathbf{X}_i)$ for all i , and order them from smallest to largest, $S_{(1)} \leq \dots \leq S_{(N)}$. Let $\hat{\gamma}_t$ be the sample $(1 - \rho)$ -quantile of performances; that is, $\hat{\gamma}_t = S_{(N - N^e + 1)}$.
3. Use the **same** sample $\mathbf{X}_1, \dots, \mathbf{X}_N$ and solve the stochastic program

$$\max_{\mathbf{v}} N^{-1} \sum_{k=1}^N I_{\{S(\mathbf{X}_k) \geq \hat{\gamma}_t\}} \ln f(\mathbf{X}_k; \mathbf{v}). \quad (7)$$

Denote the solution by $\hat{\mathbf{v}}_t$.

4. If the stopping criterion is met, stop; otherwise, set $t = t + 1$, and return to Step 2.

To run the algorithm, one needs to provide the class of sampling probability densities, the initial vector $\hat{\mathbf{v}}_0$, the sample size N , the rarity parameter ρ , and the stopping criterion. Any CE algorithm for optimization, thus involves the following two main iterative phases:

1. *Generate* a random sample of objects in the search space $\mathcal{X}$ (trajectories, vectors, etc.) according to a specified probability distribution.
2. *Update* the parameters of that distribution, based on the N^e best performing samples (the so-called *elite samples*), using CE minimization.

Apart from the fact that Step 3 in Algorithm 1 is missing in Algorithm 2, another main difference between the two algorithms is that the *likelihood ratio* term

$f(\mathbf{X}_k; \mathbf{u})/f(\mathbf{X}_k; \hat{\mathbf{v}}_{t-1})$ in Equation (5) is missing in Equation (7).

Often a smoothed updating rule is used, in which the parameter vector $\hat{\mathbf{v}}_t$ is taken as

$$\hat{\mathbf{v}}_t = \alpha \tilde{\mathbf{v}}_t + (1 - \alpha) \hat{\mathbf{v}}_{t-1}, \quad (8)$$

where $\tilde{\mathbf{v}}_t$ is the solution to Equation (7) and $0 \leq \alpha \leq 1$ is a smoothing parameter. Many other modifications can be found in [5,6] and [49], and in the list of references. When there are two or more optimal solutions, the CE algorithm typically “fluctuates” between the solutions before focusing in on one of the solutions. The effect that smoothing has on convergence is discussed in detail in [50]. In particular, it is shown that with appropriate smoothing the CE method converges and finds the optimal solution with probability arbitrarily close to 1. Necessary conditions and sufficient conditions under which the optimal solution is generated eventually with probability 1 are also given. Other convergence results, including a proof of convergence along the lines of convergence for simulated annealing can be found in [51].

Combinatorial Optimization

When the state space $\mathcal{X}$ is finite, the optimization problem (6) is often referred to as a *discrete or combinatorial optimization* problem. For example, $\mathcal{X}$ could be the space of combinatorial objects such as binary vectors, trees, paths through graphs, and so on. To apply the CE method, one needs to specify first a convenient parameterized random mechanism to generate objects in $\mathcal{X}$. For example, when $\mathcal{X}$ is the set of binary vectors of length n , an easy generation mechanism is to draw each component independently from a Bernoulli distribution; that is, $\mathbf{X} = (X_1, \dots, X_n) \sim \text{Ber}(\mathbf{p})$, where $\mathbf{p} = (p_1, \dots, p_n)$. Given an elite sample set $\mathcal{E}$, the updating formula is then [4, p. 56]

$$\hat{p}_i = \frac{\sum_{\mathbf{x} \in \mathcal{E}} X_i}{N_e}, \quad i = 1, \dots, n. \quad (9)$$

That is, the updated success probability for the i th component is the mean of the i th components of the vectors in the elite set.

A possible stopping rule for combinatorial optimization problems is to stop when the overall best objective value does not change over a number of iterations. Alternatively, one could stop when the sampling distribution has “degenerated” enough. In particular, in the Bernoulli case (9) one could stop when all $\{p_i\}$ are less than some distance ϵ away from either 0 or 1.

Continuous Optimization

It is also possible to apply the CE algorithm to continuous optimization problems; in particular, when $\mathcal{X} = \mathbb{R}^n$. The sampling distribution on $\mathbb{R}^n$ can be quite arbitrary, and does not need to be related to the function that is being optimized. However, the generation of a random vector $\mathbf{X} = (X_1, \dots, X_n) \in \mathbb{R}^n$ is usually established by drawing the coordinates independently from some two-parameter distribution. In most applications, a normal (Gaussian) distribution is employed for each component. Thus, the sampling distribution for $\mathbf{X}$ is characterized by a vector of means $\boldsymbol{\mu}$ and a vector of standard deviations $\boldsymbol{\sigma}$. At each iteration of the CE algorithm, these parameter vectors are updated simply as the vectors of sample means and sample standard deviations of the elements in the elite set [49]. During the course of the algorithm, the sequence of mean vectors ideally tends to the maximizer $\mathbf{x}^*$, while the vector of standard deviations tend to the zero vector. In short, one should obtain a degenerated probability density with all mass concentrated in the vicinity of the point $\mathbf{x}^*$. A possible stopping criterion is to stop when all standard deviations are smaller than some ϵ .

Constrained Optimization

Constrained optimization problems can be put in the framework (6) by taking $\mathcal{X}$ a (nonlinear) region defined by some system of inequalities:

$$G_i(\mathbf{x}) \leq 0, \quad i = 1, \dots, L. \quad (10)$$

To solve the program (6) with constraints (10), two approaches can be adopted. The first approach uses *acceptance–rejection*: generate a random vector $\mathbf{X}$ from, for example, a

multivariate normal distribution with independent components, and accept or reject it depending on whether the sample falls in $\mathcal{X}$ or not. Alternatively, one could sample directly from a truncated distribution (for example, a truncated normal distribution) or combine such a method with acceptance–rejection. Once a fixed number of such vectors has been accepted, the parameters of the normal distribution can be updated in exactly the same way as in the unconstrained case—simply via the sample mean and standard deviation of the elite samples. A drawback of this method is that a large number of samples could be rejected before a feasible sample is found.

The second approach is the *penalty approach*. Here, the idea is to modify the objective function as follows:

$$\tilde{S}(\mathbf{x}) = S(\mathbf{x}) + \sum_{i=1}^L P_i(\mathbf{x}), \quad (11)$$

where the $\{P_i\}$ are *penalty functions*. Specifically, the i th penalty function P_i (corresponding to the i th constraint) is defined as

$$P_i(\mathbf{x}) = H_i \max(G_i(\mathbf{x}), 0) \quad (12)$$

and $H_i > 0$ measures the importance (cost) of the i th penalty.

Thus, by reducing the constrained problem (6) and (10) to an unconstrained one ((6) with $\tilde{S}$ instead of S), one can again apply Algorithm 2. Further details on constrained multiextremal optimization with the CE method may be found in Ref. 49.

Noisy Optimization

Noisy (or stochastic) optimization problems—in which the objective function is corrupted with noise—arise in many contexts, for example, in stochastic scheduling and stochastic shortest/longest path problems, and simulation-based optimization [52]. The CE method can be easily modified to deal with noisy optimization problems. Consider the maximization problem (6) and assume that the performance function is noisy. In particular, suppose that $S(\mathbf{x}) = \mathbb{E}\hat{S}(\mathbf{x})$ is not available, but that a sample value $\hat{S}(\mathbf{x})$

(unbiased estimate of $\mathbb{E}\hat{S}(\mathbf{x})$) is available, for example, via simulation. The principal modification of the Algorithm 2 is to replace $S(\mathbf{x})$ by $\hat{S}(\mathbf{x})$. In addition, one may need to increase the sample size in order to reduce the effect of the noise. Although various applications indicate the usefulness of the CE approach for noisy optimization [7,40–42], little is still known regarding theoretical convergence results in the noisy case. Spall [53, Section A.0.0] discusses various divergence results for general types of stochastic methods. A possible stopping criterion is to stop when the sampling distribution has degenerated enough. Another possibility is to stop the stochastic process when $\{\hat{y}_t\}$ has reached stationarity [5, p. 207].

CTMCs WITH COSTS AND REWARDS

NATARAJAN GAUTAM
Department of Industrial and
Systems Engineering, Texas
A&M University, College
Station, Texas

Consider a system that can be modeled as a CTMC (continuous-time Markov chain) $\{X(t), t \geq 0\}$ such that $X(t)$ is the state of the system at time t . Note that $X(t)$ could possibly be a vector but for notational convenience we sometimes write $P\{X(t) = j\}$ with the understanding that j in those cases is also a vector. Let S be the state space of this CTMC; that is, the set of all possible values of $X(t)$ for all t . We use the notation Q to denote the infinitesimal generator matrix of the CTMC with negative values along the diagonals such that each row sums to zero. For terminologies and notation used for CTMCs see **Definition and Examples of Continuous-Time Markov Chains and Asymptotic Behavior of Continuous-Time Markov Chains** in this encyclopedia. The reader is also encouraged to consult books by Kulkarni [1] and Ross [2].

For CTMCs with costs and rewards, an additional piece of notation is necessary. Define C_i as the cost incurred by the system per unit time it spends in state i , for all $i \in S$. Notice that if C_i is negative it is equivalent to the system getting a reward (as opposed to cost) of $-C_i$ per unit time it spends in state i . Here, we present only the analysis of systems over an infinite horizon. In particular, we consider two infinite horizon cases: average costs and discounted costs. Each case has its own pros and cons that are subsequently discussed along with some examples. Then we conclude by presenting applications to performance analysis.

AVERAGE COSTS CASE

The objective here is to obtain an expression for the long-run average cost per unit time

incurred by the system. For this, we need some additional assumptions and notation. Recall that we consider a CTMC $\{X(t), t \geq 0\}$ with state space S , infinitesimal generator matrix Q , and costs C_i per unit time the system is in state i for all $i \in S$. We assume that this CTMC is irreducible and positive recurrent (together it is also known as *ergodic*) with steady-state probabilities p_j , that is,

$$p_j = \lim_{t \rightarrow \infty} P\{X(t) = j\}.$$

The p_j values can be computed by solving for $pQ = 0$ and $\sum_{i \in S} p_i = 1$, where p is a row vector of p_j values.

It is important to notice that for ergodic CTMCs, the steady-state probabilities p_j have two other meanings. First, p_j is also the long-run fraction of time the system is in state j , that is,

$$p_j = \lim_{T \rightarrow \infty} \frac{\int_0^T I(X(t) = j) dt}{T}, \quad (1)$$

where $I(\cdot)$ is an indicator function such that $I(X(t) = j) = 1$ if $X(t)$ is j at time t and $I(X(t) = j) = 0$ otherwise. Another definition of p_j is that it is the stationary probability that the CTMC is in state j . That means if the initial state of the CTMC is selected according to p_j , that is, $P\{X(0) = j\} = p_j$, then at any time t the CTMC would be in state j with probability p_j , that is, $P\{X(t) = j\} = p_j$ for all $t \geq 0$. Thus the system is considered to be stationary at all $t \geq 0$. Now we are in a position to develop an expression for the long-run average cost per unit time for this system.

Let C be the long-run average cost incurred by the system per unit time. By definition, since C is time averaged, it can be written as

$$C = \lim_{T \rightarrow \infty} \frac{\int_0^T C_{X(t)} dt}{T}.$$

We can rewrite the right-hand side of the above expression using a sum to get

$$C = \lim_{T \rightarrow \infty} \frac{\int_0^T \sum_{i \in S} C_i I(X(t) = i) dt}{T}.$$

Since the CTMC is positive recurrent, we are allowed to write the above expression as

$$C = \sum_{i \in S} \lim_{T \rightarrow \infty} \frac{\int_0^T C_i I(X(t) = i) dt}{T}.$$

Using the definition of p_i in Equation (1) and substituting, we get

$$C = \sum_{i \in S} C_i p_i. \quad (2)$$

DISCOUNTED COSTS CASE

Here, we consider the case where the costs incurred by the system are discounted at rate α . By definition, this means that if the system incurs a cost \$ \$ \$d\$ at time \$t\$, its present value at time 0 is \$de^{-\alpha t}\$. In other words, it is as though a cost of \$de^{-\alpha t}\$ is incurred at time 0. We call \$\alpha\$ as the discount factor and it is positive in sign. Having defined the discounted cost, we are ready to develop an expression for the expected total discounted cost over an infinite horizon. Let \$D_c\$ be the total discounted cost (note this is a random variable) over an infinite horizon incurred by the system. Therefore, we have by definition

$$D_c = \int_0^\infty C_{X(t)} e^{-\alpha t} dt.$$

Our objective is to obtain \$E[D_c]\$. For this, we require two notations. Let \$a_i\$ be the initial probability that the CTMC is in state \$i\$, that is,

$$a_i = P\{X(0) = i\}.$$

Notice that if the initial state of the CTMC is known, say \$j\$, then \$a_j = 1\$ and all other \$a_i\$'s would be 0. Also let \$\bar{d}_i\$ denote the expected

total discounted cost incurred over the infinite horizon starting in state \$i\$, that is,

$$d_i = E[D_c \mid X(0) = i].$$

Thus, we have

$$\begin{aligned} E[D_c] &= \sum_{i \in S} E[D_c \mid X(0) = i] P\{X(0) = i\} \\ &= \sum_{i \in S} d_i a_i. \end{aligned}$$

Note that \$E[D_c]\$ is dependent on the initial conditions via the \$a_i\$ values. So, we need to be given \$a_i\$; assuming we have that, next we show how to compute \$d_i\$ for all \$i \in S\$. On the basis of the definition we have

$$\begin{aligned} d_i &= E[D_c \mid X(0) = i] \\ &= E \left[\int_0^\infty C_{X(t)} e^{-\alpha t} dt \mid X(0) = i \right] \\ &= \int_0^\infty e^{-\alpha t} \sum_{j \in S} C_j P\{X(t) = j \mid X(0) = i\} dt \end{aligned}$$

provided \$C_j\$ is bounded. Using the column vector \$d\$ with elements \$d_i\$ such that \$d = [d_i]\$, we can write down a matrix relation

$$d = \left[\int_0^\infty e^{-\alpha t} P(t) dt \right] \bar{C},$$

where \$\bar{C}\$ is a column vector of \$C_j\$ values and \$P(t)\$ is a matrix of \$P\{X(t) = j \mid X(0) = i\}\$ for all \$i \in S\$ and \$j \in S\$. Using the Laplace–Stieltjes transform (LST) notation for \$P(t)\$, we get

$$\tilde{P}(s) = \int_0^\infty e^{-st} P(t) dt.$$

Thus,

$$d = \tilde{P}(\alpha) \bar{C}.$$

However, since \$P(t)\$ satisfies \$\frac{dP(t)}{dt} = P(t)Q\$, by taking the LST, we get \$s\tilde{P}(s) - P(0) = \tilde{P}(s)Q\$. Using the fact that \$P(0) = I\$ and solving for \$\tilde{P}(s)\$, we get

$$\tilde{P}(s) = (sI - Q)^{-1}.$$

Therefore, we have

$$d = (\alpha I - Q)^{-1} \bar{C}.$$

Notice that the matrix $\alpha I - Q$ is invertible for any $\alpha > 0$. Thus, we can compute d_i , and hence $E[D_c]$.

DISCUSSION AND EXAMPLES

It is worthwhile to contrast the discounted costs against the average costs. In the discounted cost case, the CTMC does not have to be ergodic (it could be reducible or irreducible, transient or recurrent). However, the average cost results presented require the CTMC to be ergodic, although there are ways to deal with some nonergodic cases. One of the demerits of the discounted cost case is that the results depend on the initial conditions, unlike the average cost case. Also, the discount factor in many practical situations are hard to determine. Next, we present one example for discount cost and one for average cost.

Example 1. Consider a machine that toggles between being under working condition and under repair. The machine stays working for an exponential amount of time with mean $1/\gamma$ h and then breaks down. A repair person arrives instantaneously and spends an exponential amount of time with mean $1/\beta$ h to repair the machine. A revenue of \$ r per hour is obtained when the machine is working and the repair person charges \$ b per hour.

Let $X(t)$ be the state of the machine at time t . Therefore, if $X(t) = 0$, then the machine is under repair at time t . Also, if $X(t) = 1$, the machine is up at time t . The state space $S = \{0, 1\}$. The generator matrix is

$$Q = \begin{bmatrix} -\beta & \beta \\ \gamma & -\gamma \end{bmatrix}.$$

Consider the discount cost case with discount factor α and given initial probabilities $a_0 = P\{X(0) = 0\}$ and $a_1 = P\{X(0) = 1\} = 1 - a_0$. In fact, we could assume that at time 0 the machine could be up or down (i.e., a_0 is 0 or 1, respectively). We seek to obtain an expression for $E[D_c]$, the expected total discounted cost over an infinite horizon incurred

by the system in terms of α , a_0 , a_1 , b , r , β , and γ .

Using the discounted cost results, we have

$$\begin{aligned} E[D_c] &= E[D_c | X(0) = 0]P\{X(0) = 0\} \\ &\quad + E[D_c | X(0) = 1]P\{X(0) = 1\} \\ &= d_0 a_0 + d_1 a_1, \end{aligned}$$

where

$$\begin{aligned} \begin{bmatrix} d_0 \\ d_1 \end{bmatrix} &= (\alpha I - Q)^{-1} \begin{bmatrix} b \\ -r \end{bmatrix} \\ &= \begin{bmatrix} \frac{b(\alpha + \gamma) - r\beta}{\alpha(\alpha + \gamma + \beta)} \\ \frac{b\gamma - r(\alpha + \beta)}{\alpha(\alpha + \gamma + \beta)} \end{bmatrix}. \end{aligned}$$

Notice that the notations used in the discounted costs derivation d and $\bar{C}$ are $d = [d_0 \ d_1]'$ and $\bar{C} = [b \ -r]'$. The expected total discounted cost over an infinite horizon incurred by the system is therefore

$$\begin{aligned} E[D_c] &= d_0 a_0 + d_1 a_1 \\ &= \frac{b\gamma - r\beta + (ba_0 - ra_1)\alpha}{\alpha(\alpha + \gamma + \beta)}. \end{aligned}$$

Example 2. Consider two independent and identical machines each with up times and repair times as described in Example 1. There is only one repair person who repairs the machines in the order they failed.

For this example, we seek to obtain the long-run average cost per hour incurred by the system. Recall that this is denoted by C which can be obtained using Equation (2). Let $X(t)$ be the number of working machines at time t . The state space $S = \{0, 1, 2\}$. The generator matrix is

$$Q = \begin{bmatrix} -\beta & \beta & 0 \\ \gamma & -\beta - \gamma & \beta \\ 0 & 2\gamma & -2\gamma \end{bmatrix}.$$

The steady-state probabilities p_0 , p_1 , and p_2 can be obtained by solving for $[p_0 \ p_1 \ p_2]$ $Q = [0 \ 0 \ 0]$ and $p_0 + p_1 + p_2 = 1$ as $p_0 = \frac{2\gamma^2}{2\gamma^2 + 2\gamma\beta + \beta^2}$, $p_1 = \frac{2\gamma\beta}{2\gamma^2 + 2\gamma\beta + \beta^2}$, and $p_2 =$

$\frac{\beta^2}{2\gamma^2 + 2\gamma\beta + \beta^2}$. Also, notice that $C_0 = b$, $C_1 = b - r$, and $C_2 = -2r$. Therefore, the long-run average cost per hour incurred by the system using Equation (2) is

$$C = \frac{2(\gamma b - \beta r)(\gamma + \beta)}{2\gamma^2 + 2\gamma\beta + \beta^2}.$$

PERFORMANCE EVALUATION

Here, we consider only the average costs case. An important realization to make is that the costs C_i do not have to be dollar costs. They are just the rates at which something is incurred when the source is in state i or even any time-averaged measure that depends on the sojourn time in state i . This is extremely useful in performance analysis and evaluation of systems. We illustrate this using examples.

Example 3. Consider a telephone switch that can handle at most N calls simultaneously. Assume that calls arrive according to a Poisson process with parameter λ to the switch. Any call arriving when there are N other calls in progress receives a busy signal (and hence rejected). Each accepted call lasts for an exponential amount of time with mean $1/\mu$ amount of time.

Let $X(t)$ be the number of on-going calls in the switch at time t . Clearly, the state space is $S = \{0, 1, \dots, N\}$. The infinitesimal generator matrix is

$$Q = \begin{bmatrix} -\lambda & \lambda & 0 & 0 & \dots & 0 \\ \mu & -(\lambda + \mu) & \lambda & 0 & \dots & 0 \\ 0 & 2\mu & -(\lambda + 2\mu) & \lambda & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & N\mu & -N\mu \end{bmatrix}.$$

Now, let $(p_0, p_1, \dots, p_N)$ be the solution to $[p_0 \ p_1 \ \dots \ p_N]Q = [0 \ 0 \ \dots \ 0]$ and $p_0 + p_1 + \dots + p_N = 1$. We do not write down the expression for p_i , but assume that this can easily be done by the reader.

Say we are interested in finding out the rate of call rejection. Then, we have $C_N = \lambda$

(since in state N calls are rejected at rate λ per unit time) and $C_i = 0$ for $i = 0, 1, \dots, N - 1$ (since no calls are rejected when there are less than N in system). Therefore, the long-run average number of calls rejected per unit time is $\sum_{i=0}^N C_i p_i = \lambda p_N$. We can also obtain the long-run time-averaged number of lines utilized as $\sum_{i=0}^N i p_i$.

Example 4. The unslotted aloha protocol for multiaccess communication works as follows. Consider a system where messages arrive according to a Poisson process with parameter λ . As soon as a message arrives, it attempts transmission. The message transmission times are exponentially distributed with mean $1/\mu$ units of time. If no other message tries to transmit during the transmission time of this message, the transmission is successful. If any other message tries to transmit during this transmission, a collision results and all transmissions are terminated instantly. All messages involved in a collision are called *backlogged* and are forced to retransmit. All backlogged messages wait for an exponential amount of time (with mean $1/\theta$) before starting retransmission.

Let $X(t)$ denote the number of backlogged messages at time t and $Y(t)$ be a binary variable that denotes whether or not a message is under transmission at time t . Then, the process $\{(X(t), Y(t)), t \geq 0\}$ is a CTMC. Let $p = (p_{00}, p_{01}, p_{10}, p_{11}, p_{20}, p_{21}, \dots)$ be the steady-state probabilities, that is, the solution to $pQ = 0$ and $\sum_{i,j} p_{ij} = 1$. Say, we are interested in obtaining the system throughput, that is, the average number of successful transmissions per unit time. The rate of successful transmission is μ whenever $Y(t)$ is 1 and 0 when $Y(t)$ is 0. Also, when $Y(t)$ is 1, it is not necessary that a transmission would occur, that happens only with probability $\mu/(\mu + i\theta + \lambda)$ when $X(t)$ is i . Therefore, the throughput can be computed as $\sum_{i=0}^{\infty} p_{i1} \mu^2 / (\mu + i\theta + \lambda)$. Interestingly, there is a much simpler way to obtain the throughput. If the system is stable, then in steady state the throughput must indeed be λ , using a conservation of flow argument. To obtain the time-averaged

number of backlogged messages, we can compute $\sum_{i=0}^{\infty} i(p_{i0} + p_{i1})$.

CUSTOMER RELATIONSHIP MANAGEMENT: MAXIMIZING CUSTOMER LIFETIME VALUE

MICHAEL LEWIS
Olin Business School Washington,
University in St. Louis,
St. Louis, Missouri

Customer relationship management (CRM) has been defined [1] as the “process of carefully managing detailed information about customers and all customer touch points to maximize customer loyalty.” Successful CRM requires a combination of information technology that enables monitoring of individual customers, appropriate models for predicting customer behavior and a managerial philosophy that views customer relationship as a valuable economic asset [2]. CRM applications are popular in industries such as retailing, financial services, travel, and professional sports. However, while the CRM concept and the associated systems are now common in a wide range of industries, the reality is that an inordinate percentage of CRM implementations are viewed as failures [3]. A main cause of these failures is that firms often struggle with the process of converting customer information into actionable marketing policies.

Perhaps the ultimate level of CRM is individual level or one-to-one marketing [4] where firms create customized marketing policies that maximize the economic value of each customer. Implementation of true individual level marketing that specifies marketing tactics at the level of individual customers in a manner that maximizes profitability requires sophisticated statistical and optimization techniques. Recent review articles have highlighted the need for academic researchers to develop techniques for creating individual level marketing policies that maximize customer value [5,6]. The purpose of this article is to highlight

several key concepts and metrics related to the economic value of customer assets and to discuss how management science techniques may be employed to create marketing policies that maximize the value of customer relationship assets.

CUSTOMER RELATIONSHIP MANAGEMENT

The last 15 years have seen the development of a significant body of academic literature focused on CRM. Early work focused on the development of metrics that focused on the financial value of customer assets [7,8]. This work acknowledged that customers are the ultimate source of a firm’s profits and highlighted the importance of factors such as retention rates and acquisition costs. The academic community has responded with a significant amount of research related to models that predict customer acquisition, retention, and cross-selling activity [9].

For example, customer acquisition has been modeled using binary models [10,11] or by using diffusion modeling techniques [12]. The binary logit models are notable in that they treat customer acquisition as stochastic and as a function of marketing activities. Customer retention models have been formulated in both contractual settings and in categories where purchases tend to occur at irregular intervals. For example, Bolton [13] models customer duration using a hazard modeling approach while Schmittlein *et al.* [14] develop a negative binomial distribution that can be used to predict whether a customer is still alive. In addition to acquisition and retention, customer profit ability can also be influenced by the level of a customer’s purchasing and the number of categories shopped in. Representative models of cross selling have been developed by Li *et al.* [15] for sequential purchases of financial product and Kamakura *et al.* [16] in the context of pharmaceuticals.

Perhaps the greatest limitation of these existing models is in terms of their dynamic

structures and the role of marketing actions. For instance, in terms of customer acquisition researchers have focused on the relationship between acquisition discounts and customer lifetimes [17–19]. These models begin to relate long-term behavior to initial marketing actions but tend to lack full dynamic structures. Several researchers [5,6] have noted this type of limitation and called for the development of models that create optimal individual level marketing policies across multiple campaigns [20] or over the entire customer life cycle.

CUSTOMER ECONOMICS

Two particularly important and closely related CRM profitability metrics are customer lifetime value (CLV) and customer equity [7]. Gupta and Lehmann [2] define CLV as “the present value of all current future profits generated from a customer over the life of his or her business with a firm.” CLV is therefore a measure of the profitability of individual customers. In contrast, customer equity is a measure of the value of the firm’s overall portfolio of customers. Rust *et al.* [21] define customer equity as “the total of the discounted lifetime values summed over all the firm’s current and potential customers.”

The preceding definition of customer equity with its emphasis on the discounted profitability of the firm’s present and future customers highlights that a firm’s value is the sum of the economic value of its customer relationships. Gupta and Lehmann [2] emphasize this point and discuss how customer equity can be used for valuation of firms and for merger and acquisition analyses. Other researchers have considered how customer equity considerations can be used to guide marketing decision making. Blattberg and Deighton [7] discuss the use of customer equity calculations to balance customer acquisition and retention spending levels and Rust *et al.* [21] provide models for linking marketing investments in advertising, loyalty programs, or service quality to customer equity.

Customer Lifetime Value

While customer equity links the overall value of the firm to its relationship assets, CLV operates at a more micro level and can be used at the level of the individual customer. CLV is an established concept in the database marketing industry [22] and is growing in relevance in the broader marketing community [23]. A detailed summary of the CLV literature is provided by Jain and Singh [23]. Berger and Nasr [8] give the basic structural model of CLV as

$$CLV = \sum_{t=0}^T \frac{\alpha^t(R_t - C_t)}{(1+d)^t}, \quad (1)$$

where t indexes time period, R_t is the revenue from the customer in period t , C_t is the total cost in period t , T is the total number of time periods used in the analysis, d is a single-period discount factor, and α is a retention rate. Berger and Nasr [8] also discuss procedures for adapting the calculations to account for variations in purchase frequency and revenue patterns. It should be noted, however, that the variations in purchase timing and revenue are incorporated by assuming specific deterministic patterns. These basic formulations suffer from two key limitations. First, the expressions do not account for the differences between individual customers. Second, the formulas lack mechanisms for evaluating alternative policies since retention and revenue rates are not treated as functions of marketing decisions.

Dwyer [22] makes a significant contribution by introducing the concept of a migration model. In his approach, retention rates are based on historical rates for different transaction history measures. Specifically, Dwyer computes CLV using purchasing rates that vary based on the time since a customer’s last purchase, L . This measure of time since last purchase is similar to the direct marketing concept of recency [24]. If a customer buys in a given period, at the next purchase occasion the expected purchase probability for the customer is the probability observed for customers who have purchased in the last period ($L_t = 1$). If a purchase is not made, the customer’s recency measure (time

lapsed) is incremented by one ($L_{t+1} = L_t + 1$). In this case, the purchase probability at $t + 1$ would be the historical rate for customers with a recency score of $L_t + 1$. In a migration model, calculation of CLV requires a tree-like structure to account for the cumulative effects of these probabilities.

Figure 1 shows a two-period representation of a typical migration diagram for a customer starting in the highest recency category ($L_1 = 1$). Each node in the network represents a buying decision. If a purchase is made, the customer's time lapsed reverts to one and if a purchase is not made the time lapsed increases by one. The expected first period revenue for a customer who bought in the last period ($L_1 = 1$) is,

$$\text{Revenue}_1 = \Pr(\text{buy}|L_1 = 1) * P + \{1 - \Pr(\text{buy}|L_1 = 1)\} * 0, \quad (2)$$

where P is the offered price and $\Pr(\text{Buy}|L)$ is the probability of purchase conditional to the customer being in state L . In the second period, the expected revenue must consider the probabilistic nature of period 1. The following expression accounts for the probabilities that the consumer is in either state $L = 1$ or $L = 2$ during period 2.

$$\begin{aligned} \text{Revenue}_2 = & \Pr(\text{buy}|L_1 = 1) * [\Pr(\text{buy}|L_2 = 1) \\ & * P + \{1 - \Pr(\text{buy}|L_2 = 1)\} * 0] \\ & + \{1 - \Pr(\text{buy}|L_1 = 1)\} \\ & * [\Pr(\text{buy}|L_2 = 2) * P \\ & + \{1 - \Pr(\text{buy}|L_2 = 2)\} * 0]. \end{aligned} \quad (3)$$

A primary benefit of the migration model is that revenues are based on transaction-history-based retention rates. This is an important distinction because it acknowledges the value of the information contained in observed customer behavior, and CLV estimates are computed as a function of transaction history measures. This approach allows firms to understand the relative value of different segments within the overall portfolio of customers. A difficulty with the migration model is that the calculations become cumbersome when a long time horizon is used.

Understanding the differences in CLV is useful as it allows firms to concentrate resources on their most valuable customers. A popular application of CLV is as a segmentation variable [25]. In this type of application the firm forecasts the long-term value of each member of the customer base and this estimate of future profits is used to determine customer service levels and marketing tactics. Zeithaml *et al.* [25] noted that firms such as FedEx, Bank of America, and The Limited all vary in service levels based on customer profitability estimates. In general, the notion of using CLV as a segmentation variable involves allocating resources based on the economic value of individual customers or segments.

However, while CLV estimates can be used to allocate marketing resources based on differences in forecasted customer value the models discussed thus far are not designed to guide the development of marketing policy. While it may be intuitive that firms should devote more marketing resources to high CLV customers, the CLV

Figure 1. Customer migration.

calculations discussed in this section are not designed to guide the degree to which marketing investments should vary based on CLV. In fact, it could be counterargued that high CLV customers already exhibit significant loyalty and that firms should invest in less loyal segments of customers. The fundamental issue is that the CLV calculations discussed thus far do not model CLV as a function of marketing policy.

MAXIMIZING CUSTOMER LIFETIME VALUE

A limitation with using CLV as a segmentation variable or as an input to a customer equity calculation is that marketing activity is not explicitly considered. In particular, in the preceding equations the revenues, costs and retention rate are all treated as fixed quantities rather than as functions of marketing. This is problematic as key building blocks such as revenue, R_t , are directly a function of the marketer's decisions regarding price. Likewise, the retention rate is also likely to be a function of pricing. Rather than treating CLV as a static measure, a more marketing-oriented approach to CRM would view CLV as an objective function to be maximized through the selection of marketing tactics and strategies. This view that the goal of a firm's CRM strategy should be to maximize each individual's profitability over time has been noted by multiple researchers [26–28].

Marketing and Lifetime Value

The first step in relating marketing decisions to CLV is to acknowledge that the key elements of the CLV equations are dependent on marketing tactics. In Equation (4) below, Equation (2) is rewritten to make explicit that retention rates, revenues and costs may all be functions of marketing activity, M .

$$CLV = \sum_{t=0}^T (\alpha(M_t)^t) \times (R_t(M_t) - C_t(M_t)). \quad (4)$$

Writing the equation for CLV as a function of marketing actions alters how CLV is viewed. Rather than as a static quantity

that may be used to segment customers, CLV is now an objective to be maximized by selecting marketing actions. For example, pricing may increase per period revenues but simultaneously decrease retention. The proper pricing strategy therefore involves balancing short-term revenue with long-term retention.

In addition to including marketing actions in the CLV calculation, it is also useful to include observable customer data. As noted, Dwyer's [22] migration model uses recency or time since last purchase to better account for differences in retention rates across customers. Other salient transaction history variables include a customer's past frequency of buying and the monetary value of past transactions. These three measures are collectively referred to as *RFM* (*recency, frequency, and monetary value*) and are frequently used in database marketing applications [24].

Furthermore, as transaction history measures may be reflective of underlying customer preferences it may be useful to select marketing actions based on past customer behavior. Specifically, marketing tactics may have differential effects across customer segments. This is salient as it suggests that current behavior may be determined by interactions between past buying activity and marketing actions. For instance, there is some belief that long-term customers may be less price sensitive than newer customers [29]. Equation (5) makes explicit that customer behavior may be a function of a set of state variables, X_t , that describe a customer at time t .

$$CLV = \sum_{t=0}^T (\alpha(M_t, X_t)^t) \times (R_t(M_t, X_t) - C_t(M_t, X_t)). \quad (5)$$

Maximizing Customer Lifetime Value

The goal in CRM is to determine the marketing activities that maximize each customer's lifetime value. The multiperiod time horizon of the problem, combined with the probabilistic nature of consumer behavior, means that the development of optimal

CRM marketing policies requires some form of dynamic optimization. The expression in Equation (5) provides an objective function for CRM applications.

This section briefly describes how CRM can be formulated as a dynamic programming problem. The emphasis will be on the general form of the problem rather than on solution techniques (see the sections titled “Markov Decision Processes and Dynamic Programming” in this encyclopedia). For the general case, customers are classified into one of $x_t \in X$ possible states based on transaction history at each point in time, t . The firm is assumed to be able to select a marketing action or controls, m_t , from a set of feasible actions, M . Defining the single-period profit function as $\pi(x_t, m_t)$, the single-period discount factor as d , and the decision-horizon length as T , the firm’s CRM objective function may be written as $\max_{m_t \in M} E \left\{ \sum_{t=0}^T d^t * \pi(x_t, m_t) \right\}$. This objective function is the discounted sum of single-period rewards over a T period horizon. In this expression, the single-period profit, π , is equivalent to the revenue minus cost term, $(R_t - C_t)$, in the previous CLV expressions.

The customer management goal is to determine the mapping of marketing policies to observed customer states $m(x_t)$ that maximizes CLV. For example, in the context of financial or subscription services this could entail determining the life cycle pricing strategy that optimally balances customer acquisition and retention [28]. In the case of direct marketing, the marketing problem might be to determine the mailing frequency that balances revenues with mailing costs [30].

More generally, the firm’s optimization problem is to select the sequence of marketing actions that maximizes profitability over some time horizon. The solution to the dynamic optimization problem is defined in terms of the value function, denoted as V . By definition, the value function is the greatest feasible expected payoff from time t forward, given that the customer is in state x_t at time t . The value function is equivalent to the maximum expected CLV based on optimal

selection of marketing policies:

$$CLV(x_0) = \max_{m_t \in M} E \left\{ \sum_{t=0}^T \alpha^t * \pi(x_t, m(x_t)) \right\}. \quad (6)$$

Thus far, the objective function does not include a direct statement of how customers evolve over time. In Equation (6) optimal customer value (CLV) is rewritten to make the relationship dynamics more explicit. In this equation $\Pr(x_{t+1}|x_t, m(x_t))$ is the probability a customer in state x_t transitions to state x_{t+1} , given the marketing actions specified by $m(x_t)$:

$$\begin{aligned} CLV(x_t, m(x_t)) &= E[\pi(x_t, m(x_t))] \\ &+ \sum_{\tau=t+1}^T \sum_{x' \in X} \alpha^\tau \\ &* \pi(x'_\tau, m(x_\tau)) \\ &* \Pr(x'_{\tau+1}|x_\tau, m(x_\tau)). \end{aligned} \quad (7)$$

The first term on the right side is the expected one-period profit from applying the selected marketing tactics in the current time period. The term involving the double summations represents the sum of the expected profits for future periods from $t+1$ to T . This term includes the transition probabilities through the inner summation over the customer’s potential future states (x'). The outer summation is over future time periods.

The term for the current period profits, $E[\pi(x_t, m_t)]$, is an expectation as customers’ decisions are stochastic from the firm’s perspective [31]. Purchasing probabilities also define the state-to-state transition rates, $\Pr(x_{t+1}|x_t, m_t)$ if the state variables include transaction history measures such as recency or frequency. Customer buying decisions are embedded in both the single-period profit and in the state-to-state transition probabilities.

Customer Evolution

Given that from the firm’s perspective consumers behave nondeterministically, the dynamic optimization problem is to identify the strategy that optimally controls the probabilities of transitions from one

transaction history state to another. In other words, the managerial problem is to influence the evolution of customer relationships so that customers inhabit profitable states. If the state variables are transaction history measures such as recency, frequency, and monetary value, then transition probabilities can be directly related to consumer choices. There is an extensive marketing literature devoted to modeling consumer choices (see Leeflang *et al.* [32] for a review). For example, Gupta [33] provides a model of incidence, expenditure amount, and brand choice. This type of model can generate the probabilities of future customer transaction history states as a function of the current state and marketing activities.

When the goal of marketing becomes an effort to control transaction history profiles special care needs to be taken when modeling consumer behavior. A particularly salient element of consumer decision making models is state dependence or purchase feedback effects. Roy *et al.* [34] define structural state dependence as “the influence of observed past experience with a brand on current choice probabilities.” This type of state dependence is relevant to CRM as positive purchase feedback effects provide a means for developing behavioral loyalty. If product usage increases future propensity to buy then marketing activities such as promotions can be viewed as investments in loyalty. Previous work has identified purchase feedback effects in many categories [35–37]; Seethuraman 2004. In the CRM literature, the notion of developing habit persistence through purchase feedback effects is the key element in models that have modeled customer relationships as Markov chains [38,39].

In addition to state dependence, the marketing literature has also devoted significant attention to identifying unobserved preference heterogeneity [40–42]. Unobserved preference heterogeneity refers to differences in underlying preferences across individuals that are not directly observable by the researcher. Accounting for underlying differences in preferences is critical in CRM models. The issue is that persistent choice or behavioral loyalty is often explainable by either positive purchase feedback effects

or underlying preference heterogeneity [37]. Failing to account for preference heterogeneity can be problematic as it can lead to an overestimation of the effect of past buying (spurious state dependence). Computing optimal policies using a model with spurious state dependence will result in a recommendation of overly aggressive and, therefore, suboptimal promotional policies. Given the emphasis on measures of past loyalty to define customer states in most CRM systems it is critical to account for unobserved preferences.

The marketing literature includes a variety of approaches for estimating unobserved preference heterogeneity. Kamakura and Russell [41] illustrate a method for estimating the latent segments while Rossi *et al.* [42] describe a variety of models that use hierarchical structures to estimate individual level preferences. While the estimation of individual level parameters is intuitively appealing, in practice it may be difficult to generate optimal policies for individual customers. In addition to estimating a model that generates individual level response parameters, the optimization model would also need to be executed for each individual customer. In contrast, segment level models of consumer behavior only require solving a dynamic programming model for a small number of customer segments. An important question is whether the benefits of generating individual level marketing policies justify the required additional effort.

Dynamic Programming

The definition of an appropriate objective function, marketing decision variables, and a model of consumer decision are the necessary components to treat CRM as a dynamic programming model. In terms of implementation, there are significant computational challenges. Consumer behavior is complex; the state space needed to adequately model consumer decision making can quickly become enormous. For example, a consumer state space that includes 10 levels of recency, 10 levels of frequency, and 10 levels of monetary value would involve 1000 states. If we added demographics such as sex and five levels of age, the state space

would grow to 10,000 states. If we also considered past marketing actions such as two alternative channels of customer acquisition and whether the consumer was acquired via a discount, the space would involve 40,000 states. Bellman [43] coined the term *the curse of dimensionality* to describe this exponential growth of problem size as a function of the problem's dimensions. While powerful computing systems and algorithmic advances [44,45] have made it possible to solve relatively simple customer management problems, the use of dynamic programming in CRM is still in its infancy (see the section titled "Large-scale MDPs" in this encyclopedia).

Dynamic programming models have been used primarily in the context of catalog mailing decisions [30,38,46]. In these models the firm attempts to determine the ideal mailing schedule as a function of customer transaction history. Simester *et al.* [30] find that it may be beneficial to send catalogs to customers who may not be likely to purchase in the current period. The implication is that sending catalogs not only spurs immediate purchases but may also have long-term benefits similar to advertising. Lewis [28] used a dynamic programming model to determine optimal life cycle pricing schedules for newspaper subscribers. This study found that the optimal pricing policy involves using a sequence of decreasing discounts as customer tenure increases. The studies by Simester *et al.* and Lewis illustrate a salient element of dynamic programming models of CRM. In both cases the prescribed marketing policies involve investments in customer relationships that would be neglected in myopic models.

Khan *et al.* [47] use a dynamic programming model to determine the optimal sequence and types of promotions to offer to grocery buyers. This study is executed using data from an online grocer that offers a variety of promotions including free shipping, discount coupons, and a loyalty program. In terms of findings, Khan *et al.* find that free shipping is the most effective promotion for customers who tend to purchase large amounts while coupons that offer linear discounts are more effective with customers

who usually purchase small amounts. Free shipping is also found to be the most effective promotion for reacquiring lapsed customers.

In addition, there have been a number of other recent studies that, while not explicitly stated as dynamic programming models, have developed marketing policies designed to maximize multiperiod customer revenue based on observed individual level customer data. Zhang and Krishnamurthi [48] create three-week price discount schedules for category level promotions to optimize a brand's profitability. Rust and Verhoef [27] optimize the mailings of relationship building communications. Venkatesan *et al.* [49] use Bayesian decision theory to optimally select customers based on CLV projections.

Consumer Behavior Considerations

The use of dynamic programming models to determine CLV and marketing policies highlights the marketing side of CRM. The output of these models is a set of policies that map marketing tactics to observed customer transaction history measures. This allows marketing decisions to be directly linked to the data the firm possesses about each individual customer. From a data availability and implementation standpoint this is a necessary approach. However, it should be noted that standard transaction history data may be of limited value in predicting customer behavior.

Consumers are obviously complex and it will always be a significant challenge to capture sufficient data and to develop models that account for the vagaries of consumer decision making. For example, there may be a link between customer acquisition and long-term customer retention [10]. Anderson and Simester [19] and Lewis [17] find that new customers acquired under different pricing promotions exhibit different long-term behaviors. Similarly, it may be useful to consider past marketing stimuli, customer transaction history, and interactions between marketing and past consumer decisions when analyzing customer reacquisition [18,50]. Service failures might be another area where dynamic programming models could be employed. Previous studies of the link between retention and service

failures have yielded mixed evidence [51]. In one notable study, Bolton [13] finds a positive link between unreported service failures and retention. Bolton suggests that this counterintuitive result may occur because consumers who do not report service failures may be inherently more tolerant. Including measures of service failures or complaints in a customer state space would be useful for guiding service recovery efforts. In many respects, incorporating information on service failures within a CRM optimization model would represent an effort to quantify the ill will effects that are often considered in standard newsvendor models [52]; see also article titled *Newsvendor Models*.

From a more conceptual perspective, it may be useful to define customer “states” in a more flexible manner and to consider data that may not be typically available in customer data warehouses. Advertising exposures, previous service quality [13], past promotions, and a myriad of other interactions between the customer and the brand may influence consumer loyalty. The crucial point is that it may be useful to augment customer databases with additional information that may be useful for guiding marketing policy development. For example, it may be useful to collect information on the communications that occur between brands and consumers. The development of relationships between brands and consumers is a critical but under-researched topic in CRM [53,54]. The level of the psychological or emotional connections between brands and consumers is clearly a salient element of a customer’s “state.” An open question is on how relationships between brands and consumers are best developed. This type of brand development problem could be cast as a dynamic optimization problem where the objective is to determine the optimal longitudinal communications strategy. Aaker *et al.* [55] present a field study that examines how brand personality and brand failures collectively impact relationship development. They find that differences in brand personality influence the resiliency of the consumer–brand relationship. While this study is not presented along the lines of an optimization framework that strives

to map the right marketing actions to customer states, the underlying concepts are similar in that the goal is to understand how brand personality messages and brand transgressions impact relationship strength.

In addition, many of the factors that determine customer loyalty may be unobservable. For example, the marketing literature includes models that have incorporated consumer learning and expectations [56–58]. Expectations of future quality, pricing, or catalog mailings are potentially very important. The existence of expectations highlights that consumers are active, learning entities that may themselves adopt a long-term perspective in their marketing relationships. The role of consumer expectations has long been a focal topic in services research. Specifically, the services literature has been concerned with how customer satisfaction translates into customer retention. For instance, a question has been raised regarding whether very high levels of satisfaction (“Delight”) increase future loyalty or merely raise expectations to unsustainable levels [59,60]. This type of question could conceivably be answered by adding satisfaction or other measures of service quality to a customer state space.

FUTURE DIRECTIONS

The idea of using optimization techniques to maximize the value of customers is intuitive and has been contemplated since at least the 1950s [61]. However, the computational challenges associated with dynamic programming and the costs of maintaining large-scale detailed customer databases have left these types of techniques infeasible until only recently. Many technical challenges still remain. For example, the notion of one-to-one marketing popularized by Peppers and Rogers [4] suggests that marketing policies should be determined at the level of individual customers. However, while one-to-one marketing is an intuitively appealing concept, there is little research that has studied the relative benefits and costs of one-to-one marketing programs.

Khan *et al.* [47] examine the benefits of customizing marketing policies at various levels. They use a hierarchical Bayesian approach [42] to estimate individual level response to prices and a variety of promotional instruments. The customer-specific parameters are then used to determine individual level optimal marketing policies. In addition to creating individual level policies, they also measure the benefits of determining marketing policies at the individual, segment, and overall population levels. They find that the majority of the benefits of customization can be achieved by considering transaction history measures and segment level differences. This is a salient finding because the computational challenges associated with determining individual level demand models and generating individual level marketing policies remain difficult. This is particularly true in environments characterized by large, complicated customer state spaces and in organizations that have large numbers of customers. Khan *et al.*'s findings suggest that the majority of the possible benefits from CRM can be achieved by optimizing marketing at the segment level. However, much additional research is needed on this topic and it should be noted that massive customization of marketing efforts may also have significant cost effects [62]; see also article titled **Mass Customization**.

Furthermore, while CRM systems now frequently provide the means to customize marketing policies to increasingly fine segments, there is reason to be concerned about potential backlash from customers who receive less advantageous offers. Customization of prices based on observable behavior or inferences about customer type are potentially controversial [63,64]. While basing pricing on transaction history measures is generally accepted in some contexts such as discounts to new customers or when airlines charge higher prices to business customers, other price discrimination techniques may harm customer relationships. For example, Coca Cola earned negative publicity for testing vending machines that varied prices based on the weather [65]

and Amazon.com came under fire in 2000 when consumers learned they were paying different prices for the same DVDs [66]. Because of adverse publicity Coca Cola chose not to implement the temperature-based pricing technology and Amazon.com used refunds and apologies to placate consumers who were charged higher prices in the dynamic pricing experiment. From a modeling standpoint, the key point is that it may be useful to incorporate information about the treatment of other customers into predictive models.

The computational challenges and the possibility of consumer backlash highlight the need for additional research. The incorporation of increasingly sophisticated models of consumer behavior is a particularly important avenue for future research. For example, just as firms can benefit from adopting a dynamic orientation so too can customers. If customers learn to anticipate firm actions then the firm's optimization models must also consider strategic behavior on the part of consumers [11,46]. Optimization in circumstances where consumers are strategic and forward looking is even more computationally burdensome as the problem requires the solution of a dynamic game between the firm and consumers [46].

CUSTOMIZED PRICE RESPONSES TO BID OPPORTUNITIES IN COMPETITIVE MARKETS

MARK FERGUSON
College of Management, Georgia
Institute of Technology,
Atlanta, Georgia

INTRODUCTION

Price optimization applications are typically associated with the pricing of consumer goods or the optimal design of auctions. There are a large percentage of firms, however, who face pricing decisions in a business-to-business setting where a customer requests bids from a small set of competing firms and the firms vying for the customer's business respond with a single price quote for the product or service. When the total annual sales to the firm requesting the bid does not justify a dedicated sales person on behalf of the firm responding to the bid, many firms start using analytical models to provide customized pricing recommendations on what price to offer for the business being bid upon. Customized pricing models provide a probability of winning for every possible price response, allowing a firm to balance a decreasing margin with an increasing win probability needed in a price optimization model. Examples of firms using customized pricing models include the united parcel service (UPS), when responding to bids for their small-to-medium size customers [1]; BlueLinx, when responding to requests for products from construction companies [2]; Marriot, when responding to group sales requests for their properties [3]; and Siemens, for pricing of industrial automation controls [4]. The models have also been used in the business-to-consumer market in the financial services industry, when banks determine what interest rate to offer when responding to request for mortgages, credit cards, and auto-loans [5,6]. The financial

improvement from using customized pricing models can be significant. UPS reported an increase in profits of over \$100 million per year by optimizing their price offerings using customized pricing models [7].

The value of customized pricing models comes from the ability to determine significant price segments based on a firm's historical bid history. Price segments are defined as sets of transactions, classified by customer, product, and transaction attributes, which exhibit similar price sensitivities. Customer attributes may include customer location, size of the market the customer is in, type of business the customer is in, the way the customer uses the product, customer purchase frequency, customer size, and customer purchasing sophistication. Product attributes may include product type, life-cycle stage, and the degree of commoditization. Transaction attributes may include order size, other products on the order, channel, specific competitor, when the order is placed, and what the urgency is of the bidder. In addition, some models assume knowledge of the historical and current bid-price of competing firms participating in the bid opportunity.

A common characteristic of environments where firms may employ customized pricing models is when the bidder with the lowest price does not always win the bid. Thus, markets are characterized by product differentiation where a given firm may command a positive price-premium over its competitors, depending upon the particular customer requesting the bid response. Sometimes even bids from the same customer may contain some inherent amount of uncertainty in the bid winning probability due to the bid-requesting firm randomly allocating its business to different competitors to ensure a competitive market for future bids. Because of these practices, a firm will never be able to remove all uncertainty from the bid-price response process and must work with probabilistic models.

A second common characteristic of an appropriate environment is when the size

of the bid opportunities is not large enough to justify a sales person dedicated to each customer. Instead, a single sales person may respond to multiple bid opportunities from a variety of potential customers each day. The most common alternatives to using customized pricing models is either to charge a fixed price to all customers or to have a sales agent respond to each separate bid opportunity with a customized price. Charging a fixed price leads to missed opportunities to price discrimination between different customer segments—a practice that has been well publicized for significantly increasing a firm's profit in many different industries. The other alternative, relying on a sales agent to respond to multiple bid opportunities, is also problematic. Theoretically, the sales agent should have knowledge of the market, based on a history of former bid responses with the customer requesting the bid, allowing the sales agent to respond with a customized price that optimizes this inherent trade-off between decreasing margins, due to lowering the price, and increasing probabilities of winning the bid. In reality, sales agents often do not make good trade-off decisions in these situations because of a lack of historical knowledge, the inability to process this historical knowledge into probability distributions, or misaligned incentives [8]. The judicious use of customized pricing models allows firms to capture historical bid information, analyze it, and present nonbiased price recommendations for future bidding opportunities. If there is additional information available regarding the bidding opportunity that cannot be captured in the model, the model's recommended price may serve as one of the many possible inputs to the person responsible for making the bid-response decision. Additional background and information on where customized pricing models are best applied can be found in Ref. 9.

RELATION TO TRADITIONAL PRICE OPTIMIZATION

The practice of price optimization is well known for applications where the demand

for a product over a certain period of time is correlated with the price charged for the product over the same time period. In such a situation, a firm can measure the demand at different price points for a product and use this data to estimate a price-response function. This traditional application to price optimization works well in environments where there are a large number of potential customers who may each buy a small quantity of the product (e.g., consumer retail stores) or where a small number of potential customers may purchase large quantities of a product but spread their purchases over many suppliers (e.g., commodity spot markets such as grain, steel, or oil). It is less helpful, however, in winner-take-all bidding situations that are common in business-to-business transactions, where the customer commits to purchasing a given quantity of goods or services and solicits bids from a set of firms capable of providing it. In these situations, the decision a providing firm is concerned about is not if (or how much) the customer will buy, but rather, will the customer buy from a firm as opposed to one of its competitors. Thus, the provider firm does not face a decision of what price to place on a product to attract demand, but instead, what price to quote to this particular customer for this particular bid opportunity (customized pricing).

Figure 1 shows a historical demand plot for a customized pricing scenario. Notice that the wins (indicated by values of 1) are more common for the lower prices, while the losses (indicated by values of 0) are more common for the higher prices.

The data captured in Fig. 1 is the historical win/loss data for a firm over 150 past bid opportunities for the same product. Judging from the data, it appears that the average price offered has been around \$10 per unit but the firm has historically priced it as low as \$8, and as high as a little over \$12. It also appears that a lower than average price does not guarantee a win, nor does a higher than average price guarantee a loss—there is some uncertainty in the demand. Therefore, we focus on maximizing the firm's *expected profit*, consisting of the total profit, assuming the firm wins the bid (margin multiplied by the quantity,

Figure 1. Historical demand data for customized pricing scenario.

Q) times the probability of winning a bid for a given price, which we label $\rho(P) \in [0, 1]$. Thus, the firm's expected profit is

$$\pi(P) = (P - C)Q\rho(P).$$

ESTIMATING THE PROBABILITY FUNCTION

Once $\rho(P)$ is estimated, the actual price optimization part for the problem is straight forward and differs little from the traditional linear demand problem. The difficulty, of course, lies in estimating $\rho(P)$. Before we discuss some various methods of doing so, we define some properties that any estimated function should possess. First, the function should decrease monotonically as the price increases. Second, the function should be bounded by 0 and 1 (Fig. 2).

While there are several models that provide an S-shaped probability function, the most common model used in practice is the Logit model. This model is described in Refs 7 and 9, and is compared against a competing model in Ref. 10. In its simplest form, the Logit model is represented by

$$\rho(P) = \frac{e^{\alpha + \beta P}}{1 + e^{\alpha + \beta P}}, \quad (1)$$

where α and β are parameters that must be estimated to fit the historical win/loss data. The parameter estimation is performed by minimizing the squared errors of the residuals or by using maximum-likelihood estimates. Before estimating the parameter values of the models, however, it is important to divide the historical win/loss data set into two segments; one for estimating the parameter values and the other for measuring

Figure 2. Fitted S-shaped probability function to win/loss data.

Figure 3. Marginal deal contribution versus unit price.

the fit. Similar to time series forecasting models, measuring the goodness-of-fit on the same data that the parameter values were estimated on may result in a misleadingly close fit as compared to testing the model on a holdout sample. Phillips [9] describes how each estimation method is applied to the Logit function. In general, if we define each historical bid opportunity with the subscript i (with W_i representing the indicator variable, $1 = \text{win}$ and $0 = \text{loss}$, for each bid i and P_i representing the firm's price response for bid opportunity i), the most common estimation method is to choose parameter values that maximize the likelihood of the observed values

$$\begin{aligned} \text{Max}_{\alpha, \beta} \quad & \sum_i \ln[\rho(P_i | \alpha, \beta) W_i \\ & + [1 - \rho(P_i | \alpha, \beta)](1 - W_i)]. \end{aligned}$$

Price Optimization for Customized Pricing

We now see how customized pricing probability models are used in price optimization. For the following discussion, we use the objective of maximizing expected profits. However, other strategic or operational objectives can be easily accommodated such as increasing market share or including constraints on capacity, inventory, price, or margin. In addition, the firm is assumed to be risk-neutral in this example. A risk-averse firm may prefer to optimize expected revenue with a concave utility function so as to mitigate the chances of bad individual outcomes. The price optimization problem for bid opportunity i (with

Figure 4. Probability of win versus unit price.

Q_i now representing the quantity that is requested in bid i) is

$$\text{Max}_{P_i} \quad \pi(P_i) = \rho(P_i) \times (P_i - C) \times Q_i. \quad (2)$$

Note that the margin $(P_i - C)$ is strictly increasing in price (Fig. 3) but the probability of winning the bid is strictly decreasing in price (Fig. 4). Therefore, the expected profit is often a unimodal function as shown in Fig. 5.

Determining the optimal price involves finding a global maximum for the expected profit. Since the profit function is unimodal, any search-based optimization algorithm can be used to solve for the price that maximizes profit, including the solver package available in MS Excel. The profit-maximizing price can also be found by solving for the price where the elasticity of the expected profit function is equal to the inverse of the marginal contribution ratio.

Figure 5. Expected profit versus unit price.

SEGMENTING CUSTOMERS BASED ON HISTORICAL PRICE BEHAVIOR

The basic Logit model described in Equation (1) only includes the price as a predictor of the probability of winning a bid. This model is appropriate if there are no discernable differences in the price sensitivity of a firm's customer set; every customer has the same probability, for every bid opportunity, of accepting the firm's bid at a given price. In this situation, the customized price optimization (Eq. 2) will recommend the same optimal price for every future bid opportunity. In practice, this is rarely the case—if it was, then why would the firm be applying customized pricing to begin with? A more common scenario is where a firm's sales force has historically set different prices for each bid opportunity based on certain characteristics of the bid or of the customer requesting the bid. The characteristics driving the different prices, which may even differ by salesperson within a firm, may include such things as the size of the customer (annual revenue), the length of time a firm has been a customer, the quantity requested by the bid, or the number of firms offered to submit to this particular bidding opportunity. Thus, a bid opportunity from a small customer who has had a long-term relationship with the firm and typically involves only two additional firms in the bidding process may receive a higher price quote than a large customer with little sales history who includes at least five competitive quotes in every bid opportunity. In an interesting

example of customized pricing in the banking industry, Kadet [6] describes how some banks place consumers into pricing segments and quote customized interest rates each time a potential customer inquires about a loan. It is exactly this case, when customers can be segmented on the basis of their price sensitivities, that customized pricing models provide the largest benefit.

The Logit model (1) can be expanded to include segmentation variables. To show how, we use an example from an application of customized pricing at a major credit bureau, which is a real company that we call Alpha Company because of the sensitive nature of the data set. Alpha sells credit scores of individuals to businesses that extend credit to their customers such as auto dealerships and jewelry stores. If an individual purchases his or her credit score, they pay a list price of around \$10. Businesses that purchase multiple credit scores annually often send out bids to the three largest credit bureaus, promising a minimum volume of score requests per year in exchange for a discounted price. Alpha is typically included in these bid opportunities so they have a substantial historical database that includes each past bid opportunity, the size of the minimum quantity promised in each contract, and the length of time in months that the business requesting the bid has been a customer of Alpha. We denote the quantity of each bid by Q and the length of the relationship with Alpha in months by M . In addition, we define δ as the coefficient for the quantity

parameter and λ as the coefficient for the length of the relationship. Including these new variables and coefficients into Equation (1) results in

$$\rho(P|Q, M) = \frac{e^{\alpha + \beta P + \delta Q + \lambda M}}{1 + e^{\alpha + \beta P + \delta Q + \lambda M}}. \quad (3)$$

The estimation of the coefficients ($\alpha, \beta, \delta, \lambda$) is performed through a maximum likelihood fit. However, it still remains to determine which segmentation variables should be included in the model. Just because a firm has historical data for a segmentation variable does not mean that it should be included in the model. Next, we explain how to determine whether a segmentation variable should be included.

Many different approaches to segment data exist. The number and type of segments can be determined in advance (*a priori*), such as asking the sales team what customer characteristics they use when determining the price to respond to a bid. While this knowledge (perhaps based on years of experience) should not be discounted, it should, however, be statistically tested. There are many cases where a firm implementing a customized pricing model finds, when doing so, that many of the characteristics they have historically used to segment customers are not statistically significant based on the historical sales data. Thus, it is also useful to determine (or confirm) customer segments based on data analyses (*post hoc*). Some methods for determining customer segments include nonoverlapping and overlapping clustering methods, classification and regression trees, and Expectation Maximization algorithms. A detailed analysis of these methods is beyond the scope of this article, but we refer the reader to Ref. 11 for a detailed overview. However, the easiest and most popular method is probably to run a logistic regression [12,13]. This technique is available in most statistical software packages and, similar to linear regression, a statistical significance test can be applied to the predictor variables. Running a logistic regression on Alpha's historical win/loss data results in the output shown in Table 1.

Observing the p -values in the regression output table shows that only the constant, the

Table 1. Output from Logistic Regression on Alpha's Historical Win/Loss Data

Regression Coefficients	Coefficient	p -Value
Constant	-0.270631513	0.0476
Quantity	8.33914E-06	0.6596
Price	-0.228872395	0.0094
Active months	0.362277116	<0.0001

price, and the active months are significant at the 95% level (p -value less than 0.05). Thus, the quantity variable is dropped from the model and a second regression is run using only the significant variables. The estimated coefficients of the variables from the second regression are shown in Table 2.

Substituting in the estimated coefficient values into Equation (3) leaves

$$\rho(P|M) = \frac{e^{-0.21 - 0.24P + 0.36M}}{1 + e^{-0.21 - 0.24P + 0.36M}}. \quad (4)$$

The fact that quantity was not a significant segmentation variable was a surprise to the sales team at Alpha. Prior to this study, they felt that the quantity requested in a bid was a better indicator of the price sensitivity of the customer than the length of time the customer had been doing business with Alpha. There may be other significant segmentation variables that were not included in the model, such as geographic location, and company size. Moving forward, Alpha plans on collecting additional information on each bidding opportunity so that other possible segmentation variables can be tested. In general, the number of customer attributes (segments) that can be accurately estimated depends on the amount of historical bid information available. If extensive historical data is available, greater degrees of segmentation

Table 2. Output from Logistic Regression after Removing Quantity

Regression Coefficients	Coefficient	p -Value
Constant	-0.205193446	0.0401
Price	-0.244049279	0.0028
Active months	0.363146316	<0.0001

can be achieved without compromising the accuracy and robustness of the statistical estimation of the parameter values.

While building statistically significant probability models is important, what firms really care about is improvements in profits. In the next section, we show how to test the performance of a customized pricing model.

MEASURING PERFORMANCE

We alluded to the point earlier that the historical win/loss data should be divided into an estimation set and a holdout sample set. A holdout set is critical for obtaining a realistic measure of the model's performance; it is misleading to measure the performance on the same data that was used to estimate the model's coefficients. There are two performance metrics available: percent improvement in profits over unoptimized actual profits and percent improvement in profits over unoptimized expected profits. To understand the difference between the two performance metrics, consider the following bid opportunity (Table 3) from Alpha's historical win/loss data:

The above is obtained by applying the Logit model from Equation (4) to the bid opportunity and optimizing results in an optimal price of \$5.15 for this particular bid opportunity. Substituting in the original bid price of \$3.92 into Equation (4) results in the probability of winning for the unoptimized bid of 0.24 or 24%. Substituting the optimal price results in a probability of winning for the optimized bid = 0.19.

Since Alpha's marginal cost of providing a credit score is essentially 0, the actual profit from this bid opportunity is = (original unit price – marginal cost) $\times$ order size $\times$ win/loss indicator variable = $(\$3.92 - 0) \times 240 \times 1 = \940.80 . If the original bid had resulted in a loss, the actual profit

would be 0. The original bid expected profit = (original unit price – marginal cost) $\times$ order size $\times$ probability of win at the original bid price = $(\$3.92 - 0) \times 240 \times 0.24 = \225.79 . Note that the expected profit is always smaller than the actual profit when the bid was won, and is always larger when the bid was lost. The optimized bid expected profit = (optimized price – marginal cost) $\times$ order size $\times$ probability of win at the optimized bid price = $(\$5.15 - 0) \times 240 \times 0.19 = \235.60 . These calculations can then be used to calculate the two performance measures for this bid opportunity as follows:

- Percent improvement in optimized bid expected profits over unoptimized bid actual profits = $(\$235.60 - \$940.80)/\$940.80 = -0.75 = -75\%$
- Percent improvement in optimized bid expected profits over unoptimized bid expected profits = $(\$235.60 - \$225.79)/\$225.79 = 0.04 = 4\%$.

The calculations above should be performed for every bid opportunity in the holdout set and the sum of each measure (over each bid opportunity in the holdout set) can then be used as a measure of performance for the model. For this data set (holdout sample equal to 160 historical bids), the total percent improvement in actual profits was 137% and the total percent improvement in expected profits was 112%.

IMPLEMENTING A CUSTOMIZED PRICING OPTIMIZATION PACKAGE

Thus far, we have focused on the technical aspects of customized pricing optimization. What is clearly evident, however, from the presentations by individuals whose firms

Table 3. Example: Historical Bid Opportunity

Bid	Win	Order Size	Active Months	Original Bid	Optimal Bid	Probability of Win at Original Bid	Probability of Win at Optimized Bid
451	Y	240	0	\$3.92	\$5.15	0.24	0.19

have implemented customized pricing models, is that the most difficult part of an implementation is not the proof of the value of the system; nor is it building the models and performing the price optimizations. Instead, the most quoted difficulty involves the acceptance of the system's price recommendations by the existing sales team [1,2,4,14]. The removal of some decision-making authority away from individuals to a more automated system is problematic in any environment; however, it is particularly difficult for pricing since the sales team may feel that the ability to generate customized price quotes is a large part of the value they bring to the firm and their incentive system (often a commission based on total revenue) may not match the profit maximization objective of a customized pricing optimization system.

Given the almost certain cultural issues and expected resistance to a system implementation, are there best practices that may be applied to help mitigate these problems? It is clear that there are some practices that seem to help, based on the same panel discussions referenced above. The most frequently suggested technique is to treat the customized price optimizer as a decision support tool for the sales team rather than a system that will automatically set prices for all future bid opportunities. No automated pricing system will ever completely replace the ability of humans to factor in extenuating circumstances or information that is not captured in the historical sales data. Sales personnel often overemphasize the value of human judgment so there needs to be some incentive to follow the recommendations of the pricing models. One such incentive that has worked for several firms is to track the frequency that a sales person sets a price within the recommended range from the pricing model and then publish these results along with the monthly profits made by each sales person. If, as expected, the sales personnel ranked the highest for pricing within the recommended price ranges are also ranked the highest for monthly profits, then the rest of the sales team will copy this practice to improve their own performance.

CONCLUSIONS

To summarize, the following steps are involved in building a customized pricing optimization model:

1. Start with a historical data set of the firm's previous bid opportunities for the product of interest. This data set should include both wins and losses along with the price submitted for each bid opportunity and any other segmentation data available on the customer or bid. The historical data set should be randomly divided into two distinct sets: the first for estimating the model parameter values and the second for performance evaluation (the holdout data).
2. A win/loss probability model, such as the Logit model, should be developed that includes coefficients for any segmentation variables.
3. Using the estimation set from the historical data, the parameter values for the probability model should be estimated using maximum likelihood estimators. This can be done by running a logistic regression if a Logit model is used for the probability model. The output from the regression will identify the segmentation variables that are significant.
4. After selecting the win/loss probability model that provides the best fit for the holdout sample data, use this model to optimize the bid prices for all the bids in the holdout set from the historic data.
5. Percent improvements over expected profits and over actual profits can then be calculated using the holdout data to measure the model's performance.

While customized pricing models hold great potential for substantially increasing profits, any firm considering adopting price models for customized pricing needs to be aware of its limitations. The models behind customized pricing assume that the bid opportunities are exogenous and are not affected by the bid responses suggested

through the optimization. In reality, a firm's pricing strategy may have a significant impact on customer retention, especially if the optimization model recommends consistently pricing higher than the competition for a particular customer class. Also, the optimization models do not assume any strategic response from the firm's competitors. Instead, they assume that the actions of competitors will stay the same as they were during the time period covered by the historical data set. In reality, competitors may react to a firm's new pricing strategy causing the historical bid opportunity data to be unrepresentative of future bid price responses. To help detect these possibilities, mechanisms should be put in place to monitor and evaluate the performance of the models over time. If competitors change their bid-pricing behavior due to the implementation of a customized pricing solution, more involved models using concepts from game theory should be employed.

INTRODUCTION

The cumulative sum (CUSUM) statistic, which was first introduced by Page [1], is an unweighted sum of all past observations.

$$S_t = \sum_{i=1}^t (X_i - \mu_0),$$

where X_i is the observation at time i and μ_0 is the targeted mean of the process. The initial purpose of the CUSUM statistic is to detect changes of the mean level in the sequence of X_t . Intuitively, if the mean of the process is larger than μ_0 , the mean path of $\{S_t\}$ directs upward when plotted along time. If the process mean level is smaller than μ_0 , the sequence of $\{S_t\}$ will show a downward trend. Page [1] proposed to issue an alarm at time t when $S_t - \min_{1 \leq i \leq t} S_i > h$ or $\max_{1 \leq i \leq t} S_i - S_t > h$, where h is a positive threshold value to control the false alarm rate.

Since its first introduction in quality control, the CUSUM chart and associated algorithms have found tremendous applications and proved successful in detecting process changes. Basseville and Nikiforov [2] and Hawkins and Olwell [3] discussed a

few engineering areas including quality control in manufacturing and production improvement, condition monitoring of inertial navigation systems, seismic signal processing and segmentations of signals, as well as vibration monitoring of mechanical systems. In manufacturing systems, by assuming two states of a production process, in control and out of control, production decisions have to be reached sequentially to decide if the process has entered the out-of-control state. Similarly, in navigation systems, using sensor information and the motion equations to estimate the coordinates and the velocities of moving objects is critical for object tracking and control. In signal and image processing applications, seismic data processing and signal segmentations are usually the first processing step in determining *in situ*, the geographical coordinates and boundaries. This article will briefly discuss several other applications in disease surveillance, sensor networks, and forecasting applications. Within these diversified applications, as a statistical tool, the CUSUM statistic is of great interest in three common problems, (i) detect abrupt process changes, (ii) estimate the effect of changes, and (iii) track and forecast dynamic systems. The goal of the decision rules is generally the quickest detection of the disorders with as few false alarms as possible.

CUSUM STATISTICS, CHANGE-POINT PROBLEM, AND SEQUENTIAL TESTING

Page's CUSUM statistic stems on Wald's [4] sequential probability ratio tests of whether the process mean has changed to some specific value μ_1 . In general, assume that X_t has probability density $f(x, \theta)$, where θ is the parameter of the probability distribution. To test if the parameter has changed from θ_0 to θ_1 at time i given a sequence of observations $\{X_t\}$, the generalized likelihood ratio (GLR)

statistic can be developed as

$$W_t = \max_{1 \leq i \leq t} \Lambda_i^t,$$

where $\Lambda_i^t = \prod_{k=i}^t f(X_k, \theta_1)/f(X_k, \theta_0)$, which triggers an alarm when $W_t > h$. When X_i is normally distributed with mean μ and variance 1, the GLR test is equivalent to the CUSUM statistic S_t by searching the change-point time when maximizing the GLR statistic [1]. Barnard [5] also developed a V-mask to judge crossing the boundary. Kemp [6] further showed that the use of V-mask on a CUSUM chart is equivalent to monitoring the two CUSUM

$$\begin{aligned} W_t^+ &= \max(W_t^+ + X_t - \mu_0 - k, 0), \\ W_t^- &= \max(W_t^- - X_t + \mu_0 - k, 0), \end{aligned}$$

with a horizontal limit h , where k is a positive reference value. The reference value k is usually set at half of the mean shift magnitude. The threshold value h is generally determined to maintain a prespecified in-control average run length (ARL). Statistically, ARL is the expected number of observations before an alarm is triggered. A larger in-control ARL and a smaller out-of-control ARL are preferred in practice. In general, when X_t follows distributions other than Gaussian, the above CUSUM forms may be adjusted.

The widespread applications of the CUSUM statistic is mainly due to its optimality for detecting a prespecified mean shift, either small or large [7–9]. Theoretically, when X_t follows a standard normal distribution, an optimal CUSUM chart can be obtained for detecting a mean shift of size δ in X_t , if the reference value $k = \delta/2$. In practice, the CUSUM chart may perform poorly when actual mean shift is different from $2k$. When the shift size is unknown, Siegmund [10] proposed the GLR statistic optimized not only with reference to the change-point time, but also with reference to the shift magnitude. Unlike the CUSUM statistic, this GLR statistic involves heavy computations and is hard to implement in practice.

CUSUM AND STATISTICAL PROCESS CONTROL (SPC)

When the shift magnitude is unknown in industrial practice, several modifications and simplifications of the CUSUM charts have been proposed to achieve good performance over a range of mean shifts. Several authors suggest running multiple CUSUM charts simultaneously, each optimized for a different size mean shift [11–14]). Hawkins *et al.* [15] and Lai [16] investigated a change-point model by assuming a prior distribution of the shift size. Sparks [13] proposed an adaptive cumulative sum (ACUSUM) procedure by dynamically adjusting the reference value of the conventional CUSUM chart for detecting a range of mean shifts. Luo *et al.* [17] also developed an ACUSUM chart with variable sampling intervals.

Another challenge facing industrial applications of the CUSUM schemes is the assumption of constant parameter shifts. Linear drift is a common type of mean shift that has been investigated widely. Other types may include residuals from time series models [18]. To track dynamic parameter changes, weighting cumulative sums is a natural generalization of the traditional CUSUM charts for different purposes. Yashchin [19] proposed two different weighted cumulative sum (WCUSUM) charts for monitoring process locations when sample sizes vary over time and when the process mean is subject to linear drifts rather than step changes. Cumulative score (Cuscore) statistic proposed by Box and Ramirez [20] is another example of WCUSUMs for detecting feared fault signals in a white noise process. Although the Cuscore statistic is a generalization of the traditional CUSUM statistic, the former critically depends on the starting point of the change, whereas the latter does not. Owing to this reason, it often requires the assumption that the number of the suspected periods at which a change may occur is small or known *a priori*, so that a Cuscore chart can be started at any such suspected period. Shu *et al.* [21] proposed a WCUSUM control chart for monitoring dynamic mean shifts from time series models.

Another important application of the CUSUM charts in industrial process control is to detect process variance changes, which, however, has not been popularly discussed [22]. Logarithm of sample variance has been traditionally suggested for CUSUM monitoring procedures due to the property that it is approximately normally distributed with a constant variance [23]. Recently, research has shown that the CUSUM chart based on the sample variance itself is more efficient than that based on the logarithm of the sample variance [24].

MULTIVARIATE CUSUM (MCUSUM)

It is natural to extend the univariate CUSUM charts to monitoring multivariate data. Woodall and Ncube [25] defined a multiple CUSUM method under multivariate normal distributions. The idea is similar to considering the maximum over the CUSUM statistic of individual responses. Similar to the T^2 statistics [26], Crosier [27] proposed a multivariate cumulative sum (MCUSUM) method as charting the T^2 statistic over the CUSUM statistic of individual responses. Pignatiello and Runger [28] proposed two MCUSUM statistics, one of which is defined as the CUSUM statistic of the univariate T^2 statistic from the multivariate vector of responses. While some simulations have been conducted for evaluation purposes, it is not clear which CUSUM statistic has better performance in general. Jiang and Tsui [29] related the T^2 chart, M-chart, and regression-adjusted chart [30] and showed that the performance of a multivariate control chart may depend on correlation of the variables as well as the direction and magnitude of the process shift. Although the discussion was limited to Shewhart-type control charts, the conclusions can be generalized to MCUSUM charts. They further proposed a hybrid method that combines the T^2 chart and regression-adjusted chart for better performance.

Under various applications, different CUSUM statistics have been proposed for monitoring multistreams (regions) data. Tarakovsky *et al.* [31] studied a simpler

CUSUM statistic similar to the one proposed by Sonesson [32]. Their idea is to first compute the temporal CUSUM statistic for each region, then to define the overall test statistic as the maximum over the individual CUSUM statistic over the multiple streams. Raubertas [33] developed another CUSUM statistic: Instead of computing the temporal CUSUM statistic for each region, he proposed to compute the simultaneous CUSUM statistic for the center and four (or fewer) adjacent regions for each region center, and then define the overall testing statistic as the maximum over these simultaneous CUSUM statistics.

MCUSUM AND DISEASE SURVEILLANCE

Scan statistic is a special class of MCUSUM statistic for spatiotemporal surveillance. The objective for disease surveillance is to detect and signal outbreaks as early as possible, which may occur at certain regions and last for certain amount of time. Kulldorff *et al.* [34] and Kulldorff [35] proposed retrospective and prospective scan statistics, respectively, based on the basic theory for the spatial case explained above. The spatiotemporal scan statistic approach can be regarded as an extension of the spatial method. The cycle scanning the area of interest is attributed a “height” so that a scan cylinder is created. The height corresponds to the time window that is scanned. The cylinder height can vary just as the cycle radius with one end fixed to the most recent time for the prospective scan case, and both ends free for the retrospective case. The time window also needs to lie within certain constraints.

Woodall *et al.* [36] reviewed and examined various scan statistics used for spatiotemporal surveillance. They pointed out that this method can only work if a cluster contains at least two incidence counts because otherwise the likelihood function could be maximized by decreasing the size of the cycle while centered on a single data point. They also stated that for the prospective scan case, only very few performance evaluations have been undertaken; and they proposed performance measures to compare this method to

statistical process control (SPC) methods. In addition, a robust and detailed evaluation of the spatiotemporal scan statistic seems to be hard to obtain, given the current state of research.

By extending the scan statistics in Kulldorff [35], Sonesson [32] proposed a CUSUM method for timely detection of emerging clusters of diseases. On the basis of a general likelihood function, he defined a general CUSUM statistic as the maximum over all individual CUSUM likelihoods over all possible subsets of regions (variables). He showed that the CUSUM likelihood statistic conditional on a given center region with a fixed radius (or nearest neighbor) can be written in the traditional CUSUM form with a recursive formula. He also showed that Kulldorff's spatiotemporal scan statistic method could be interpreted as a conditional likelihood approach given the total number of incidents and given that the parameters are known. Simulation studies were conducted to compare Sonesson's CUSUM with Kulldorff's scan statistic with known parameters, and the performance of the CUSUM was found to be superior. This result is not surprising as the CUSUM statistic has been shown to be optimal under certain conditions.

In disease surveillance, the SPC-based spatiotemporal surveillance problem has been studied by just a few researchers. Rogerson [37] presented some control chart-based work on the spatiotemporal regional case. He extended the retrospective method of Tango [38] to a prospective application using a CUSUM method. Rogerson *et al.* [39] considered the spatiotemporal problem for which the counts in the subregions are correlated at each particular time, with the correlation decreasing as the distance between the subregions increases. They compared the performance of the use of multiple CUSUM charts [25] for each region against an MCUSUM method [27].

Other applications of CUSUM methods in health care include risk-adjusted monitoring schemes for clinical practices and surgical performance evaluation [40,41]. Owing to the heterogeneity of the baseline patient risk, the surgeon's performance may be masked by the heterogeneity, which makes it slow

to respond to performance changes. Grigg and Farewell [42] provide an overview of risk-adjusted charts and present a comparison based on an empirical case from a single data set. Tsui *et al.* [43] provided a comprehensive review of applications of SPC in health care, public health, and syndromic surveillance.

MCUSUM AND SENSOR NETWORK APPLICATIONS

The CUSUM statistic/procedure has been successfully applied in Mei [44] to tackle the decentralized quickest change detection problems in sensor networks, which have many important applications, including multisensor data fusion, mobile and wireless communication, surveillance systems, and distributed detection.

Specifically, in a widely used configuration of sensor network systems, at each time step, each of a set of local sensors receives an observation and then sends a sensor message to a central processor, called the *fusion center*, which makes a final system-wise decision when observations are stopped. In order to reduce cost and increase reliability, it is required that the sensor messages are "quantized" in the sense of belonging to a finite alphabet (perhaps binary). This limitation is dictated in practice by the need for data compression and limitations of channel bandwidth. In decentralized quickest change detection problems, it is assumed that at some unknown time, the distributions of the sensor observations change abruptly and simultaneously at all sensors. The goal is for the fusion center to utilize the "quantized" sensor messages to detect the change as soon as possible over all possible protocols for generating sensor messages and over all possible decision rules at the fusion center, under a restriction on the frequency of false alarms.

One novel decentralized scheme developed in Ref. 44 is for each local sensor to calculate the local CUSUM statistic at each time step, and then send binary "sensor decisions" $\{0,1\}$ to the fusion center, depending on whether the local CUSUM statistic exceeds

the local threshold. The fusion center then combines all local sensor decisions using a “consensus” rule, that is, it stops and decides that a change has occurred as soon as all local CUSUM statistics exceed their respective local thresholds. A surprising theoretical result in Ref. 44 is that with suitably chosen local thresholds, this decentralized scheme has the same (first-order) asymptotic performance as the optimal centralized scheme that has access to all the sensor observations, although it may perform poorly in some practical situations because of slow asymptotic convergence. It is interesting to note that in the definition of the proposed decentralized scheme, one cannot replace the CUSUM statistic by other well-known change-point detection statistics such as exponentially weighted moving average (EWMA) or Shiryaev–Roberts statistic [otherwise the asymptotic optimality properties will no longer hold, see Remark 4 on p. 2674 of Mei [44]]. Further research is needed to find fairly simple decentralized schemes that are not only asymptotically optimal but also have good performance for practical values.

CUSUM AND FORECASTING APPLICATIONS

One of the major issues in forecasting is the necessity of defining the correct moment for intervening in forecasting procedures that have begun to produce systematic biases. In principle, interventions are called for when the size of forecasting discrepancies increases due to a change in the reality of the forecasting environment. It is thus straightforward to extend the use of control charts for monitoring forecast errors. Trigg [45] first provided a rigorous treatment in monitoring forecast errors. CUSUM forecast monitoring schemes have been employed since 1959, following the procedures of Harrison and Davies [46]. Gardner [47] compared the CUSUM chart for residuals and other smoothed-error forecast monitoring schemes. West and Harrison [48] developed a Bayesian framework that applies the CUSUM scheme to track forecasting errors in predicting complex time series models.

In forecasting economic time series, ignoring structural breaks, which occur in the time

series, significantly reduces the accuracy of the forecast. Brown *et al.* [49] proposed several CUSUM tests based on recursive residuals and squares to identify a single structural break in long memory processes. Inclán and Tiao [50] used the CUSUM for multiple structural break detection. Pesaran and Timmermann [51] proposed reverse CUSUM for detecting the most recent break. Pang and Ting [52] further extended the reverse CUSUM and proposed a data selection method for time series prediction. Although different alternative models are assumed, the CUSUM statistic is obtained based on the likelihood ratio test in principle.

DISCUSSIONS

CUSUM charts and methods have been recognized to be very powerful in process monitoring and forecasting. They have been successfully applied to many applications including manufacturing, health surveillance, and sensor networking. Much research has been done in both theoretical and application domains. In theory, there remains a big challenge in optimality aspects of various developed charting procedures in both univariate and multivariate cases. In applications, there is a great potential for developing additional CUSUM methods for complex monitoring problems, such as spatiotemporal surveillance of infectious diseases [43] and activity monitoring of business processes [53].

CZECH SOCIETY FOR OPERATIONS RESEARCH

PETR FIALA
Department of Econometrics,
University of Economics,
Praha, Prague, Czech
Republic

The Czech Society for Operations Research (CSOR) was registered at the Home Office of the Czech Republic on October 10, 1993 as a profession society seated in Prague.

The objectives of the Society are:

- to maintain the development of the Operations Research (OR) as a branch;
- to maintain the education and the professional activities specializing in the field of OR;
- to organize and coordinate the cooperation with partner societies abroad.

The membership of the Society consists of private persons (individual membership) and corporations (collective membership). The membership is conditioned by professional qualification. The membership fee is annually approved by the Council of the Society. Reduced fee is available for the elderly and students.

The CSOR is very small society with approximately 40 members. Council of the CSOR consists of the president, two vice presidents, and six members of the Council. Presidents are elected for the period of two-years.

PAST PRESIDENTS

1993–1995 Miroslav Maňas, University of Economics, Prague
1995–1997 Karel Zimmermann, Charles University, Prague
1997–1999 Jaroslav Ramík, Silesian University, Opava

1999–2001 Jiří Beck, University of West Bohemia, Pilsen

2001–2003 Jan Pelikán, University of Economics, Prague

2003–2005 Jana Hančlová, Technical University of Ostrava, Ostrava

2005–2007 Josef Jablonský University of Economics, Prague

2007–2009 Petr Fiala, University of Economics, Prague

CSOR ACTIVITIES

Main activities of the CSOR are annual conferences, seminars, and consultations with firms. The annual conferences, Mathematical Methods in Economics, are organized by the Czech Society for Operations Research and the Czech Econometric Society; mathematical methods in economics is a traditional meeting of professionals from universities and business who are interested in the theory and applications of OR and econometrics. The conferences take place in various Czech cities in the first half of September. The conferences are regularly attended by more than 100 participants from Czech Republic and other countries. The main themes of the conference include

- Operational Research
- Econometrics
- Quantitative Management Methods
- Simulations
- Mathematical Modeling
- Process Optimization

In the year 2009 an informal seminar for the Society members on results and problems in education, science, and practice of OR was organized for the first time. The activity received a very positive reception by members. The informal seminars should be a tradition in the forthcoming years, and the Doctoral Dissertation Award for OR students is presented at this conference.

The CSOR is a member of IFORS and EURO. Representatives of the CSOR attend regularly the councils of these associations. The CSOR cooperates by editing of the quarterly published *Central European Journal of Operations Research*. Members of the Society are granted the subscription of the journal. The Society has strong contacts with the Slovak Society for Operations Research. There are very often visits between the Societies and members of both societies frequently participate in each other's conferences. The CSOR cooperates closely with the Austrian Society as well.

The main international activity organized by the Czech Society for Operations Research was the 22nd European Conference on Operational Research EURO XXII in 2007. The conference was organized by the CSOR in cooperation with the University of Economics, Prague. The conference was held in the campus of the University of Economics which is situated very close to the Prague historical center. The conference was very successful, attended by more than 2000 participants from all over the world.

DAMAGE, STRESS, DEGRADATION, SHOCK

WALTRAUD KAHLE
Department of Mathematics,
Otto-von-Guericke University,
Magdeburg, Germany

INTRODUCTION

Investigating the lifetime of products or biological organisms that are affected by degradation, damage, stress, or shocks it is often necessary to consider the development of a stochastic process which models ageing, wearing, damage accumulation, and other changes of the state. In the following, we will call such processes *degradation models*.

The applicability of a purely lifetime-based reliability analysis is limited due to several reasons. Collecting a sample of lifetime data is often expensive. In applications from engineering, observed lifetimes are frequently very long. Furthermore, there are many products for which breakdown causes serious difficulties. When designing the mathematical model of a degradation process, the following steps have to be taken:

1. Starting from basic technical considerations, a suitable mathematical model for the degradation measure process $Z(t)$ has to be defined. For instance, the hypothesis of additive degradation accumulation may be used. In this case, we may select the class of homogeneous processes with independent increments as a suitable model class. Another possibility is the description of degradations by shock models.
2. By applying the level exceeding theory, it is possible to find the type of lifetime distribution, that is, the distribution of the time at which the stochastic process firstly exceeds the degradation level.

3. The parameters of the selected model have to be estimated by means of samples related to the degradation measure $Z(t)$.
4. Estimations of the parameters of lifetime distribution can be obtained from the estimated parameters of the model $Z(t)$, if the limit level of degradation is known.

As example, one can model the degradation $Z(t)$ by the linear path model

$$Z(t) = t/A,$$

where A is a positive random variable [1,2]. A generalization and statistical analysis by nonparametric methods of estimation from joint linear degradation and failure time data with partial renewals and competing failure modes is given in Ref. 3.

Another widely used model is the gamma degradation process: a continuous-time stochastic process with independent and gamma-distributed increments. A detailed description and many further references are given in Refs 4–6 (see also ***Accelerated Life Models***).

In the next section, we describe in more detail continuous degradation models based on a Wiener process with drift.

Another widely used class of models are *shock models* [7]. The standard assumptions in shock models are that the failure is related either to the cumulative effect of a large number of shocks or that failure is caused by a shock that exceeds a certain critical level, or a mixture of both of them. Asymptotic properties of a wide class of models are given in Ref. 8. In the last section, we consider a general *parametric* shock model.

CONTINUOUS DEGRADATION MODELS

The choice of the mathematical model for these degradation processes is based on the assumption of an additive accumulation of

degradation with constant wear intensity. Regarding every degradation increment as an additive superposition of a large number of small effects, we can assume the degradation process to be normally distributed. Therefore, the degradation measure $Z(t)$ can be described by the following model [9]:

$$Z(t) = z_0 + \sigma W(t - t_0) + \mu \cdot (t - t_0), \quad t \geq t_0 \quad (1)$$

with

z_0 = constant initial degradation ($z_0 \in \mathbb{R}$),
 t_0 = beginning of the degradation ($t_0 \in \mathbb{R}$),
 μ = drift parameter ($\mu \in \mathbb{R}$),
 σ = variance parameter ($\sigma > 0$),
 $W(t)$ = standard Wiener process on $[0, \infty)$.

We suppose that a failure of a product will occur if the degradation process arrives at a certain boundary degradation level, which, in general, is unknown. For a given boundary level h , the lifetime T_h of the product is then determined as the instant at which the degradation process $Z(t)$ exceeds the level h for the first time:

$$T_h = \inf\{t \geq t_0 : Z(t) \geq h\}. \quad (2)$$

It is well known that for $z_0 < h$ the lifetime T_h follows an inverse Gaussian distribution with the Lebesgue density function

$$f_{T_h}(t) = \frac{h - z_0}{\sqrt{2\pi\sigma^2(t - t_0)^3}} \times \exp\left(-\frac{(h - z_0 - \mu(t - t_0))^2}{2\sigma^2(t - t_0)}\right) I_{[t > t_0]}, \quad (3)$$

where $I_{\{\cdot\}}$ denotes an indicator variable, assuming the value 1 if the relation in brackets is true, and the value 0 otherwise. Obviously, P^{T_h} is the Dirac measure ε_{t_0} concentrated at t_0 if $z_0 \geq h$. To estimate the parameters of this model, we can have several kinds of observations:

1. The increments of the degradation process are observed.

In this case, the likelihood function of the observation is a product of Gaussian

densities. It is possible to estimate the parameters of the degradation process μ , σ^2 , z_0 , and t_0 , but it is impossible to estimate the degradation level h . Note that neither the same distance between observation points nor observation of all realizations at one and the same time points are required. Parameter estimations can be found if the observations are taken at individual time points in each realization.

2. The failure times are observed.

In this case, we get the classical likelihood function from a sample of inverse Gaussian distributed random variables. From this likelihood function, we can estimate the parameters μ , σ^2 , and t_0 . The degradation reserve $h - z_0$ must be given in advance.

3. The sample includes both process increments and failure times.

Assume that the sample consists of N failure times and $\sum_{i=1}^n m_i$ increments, being mutually independent. Then, the likelihood function is the product of the likelihood functions mentioned below. In case the failure times and process increments belong to the same process, the likelihood function is more complicated. In this case, the density of a process increment is a conditional density under the assumption that the process does not cross the degradation level in the actual time interval. If the sample includes both process increments and failure times, then it is possible to estimate all the parameters of the model.

These models and their parameter estimation are described in Kahle [9] and Kahle and Lehmann [10]. A similar model and its application in medicine is described in Doksum and Normand [11]. Several generalizations of this simple model were given. It is possible to include measurement errors [12], or to transform the time scale [13]. It is also possible to consider bivariate models [14].

The advantages of using the Wiener process and its generalizations for describing the degradation process are its simple form (at least for the univariate Wiener process), and

secondly, a statistical analysis can be carried out for observations at any discrete time points. But these models have also disadvantages: It is possible that the degradation is decreasing in any interval and this is difficult to interpret in practical applications. The second disadvantage is that these models become very complicated if a nonlinear drift is assumed. But for many products, we can expect an increasing degradation which becomes faster over time.

PARAMETRIC SHOCK MODELS

Introduction

This model deals with a degradation process (Z_t) whose paths are monotonically increasing step functions. We make use of marked point processes $\Phi = ((T_n, X_n))_{n \geq 1}$. A mathematical foundation is given by Last and Brandt [15] and Anderson *et al.* [16]. The cumulative process (Z_t) is assumed to be generated by a doubly stochastic Poisson process (T_n) . This process was introduced by Cox [17]. It was proposed as a model in risk theory by Cramér [18]. Grandell [19] gave a detailed discussion of doubly stochastic Poisson processes and their impact on risk theory. Further applications may be found in reliability theory, medicine, and queueing theory [16, 20, 21].

There is a stream of papers concerning shock models. Applications were given—among others—by Sobczyk [22] and Esary *et al.* [23]. Further papers dealing with shock models are Refs 24–33. In the present paper, we assume cumulated intensities of (T_n) given as a random multiple Y of a deterministic function η . Frequently, these stochastic intensities are more realistic than the deterministic intensity of a Poisson process. Each realization of the random variable Y leads to an other individual intensity of (T_n) which could be a result of individual environmental conditions or of the individual frailty of the item.

Our aim is to describe suitable models for degradation accumulation, to calculate the corresponding cumulative degradation at time t , to consider a first passage time, and to determine its distribution.

Modeling Degradation by Marked Point Processes

Let $[\Omega, \mathcal{F}, P]$ be a fixed probability space and let $\{\mathcal{F}_t\}$ be a filtration in $\mathcal{F}$. The random variable T_n ($n \geq 1$) is the time of the n th shock. We suppose

$$\begin{aligned} T_n < T_{n+1} & \quad \text{if } T_n < \infty \quad \text{and} \\ T_n = T_{n+1} & = \infty \quad \text{otherwise.} \end{aligned}$$

The size of the n th increment of the cumulative degradation process $(Z(t))_{t \geq 0}$, is given by a nonnegative random variable X_n ($n \geq 1$). Thus,

$$Z(t) = \sum_{n=1}^{\infty} I(T_n \leq t) \cdot X_n$$

describes the total amount of degradation at time t . The sequence $\Phi = ((T_n, X_n))$ is called a *marked point process*, and $\Phi(t)$ is defined as the random variable representing the number of events that occurred up to time t . Frequently, it is of interest to discuss the first passage problem that the process (Z_t) exceeds a prespecified constant threshold level $h > 0$ for the first time. It is also possible to regard a (random) state of first X_0 at time $T_0 := 0$. Then the corresponding first passage time Z^h is given as

$$Z^h = \inf \left\{ t : \sum_{n=0}^{\infty} I(T_n \leq t) \cdot X_n \geq h \right\}. \quad (4)$$

Let us mention that Z^h coincides with some T_m for $m \in \mathbf{N}$.

We consider the filtration $\{\mathcal{F}_t\} = \{\mathcal{F}_t^{\Phi}\} \vee \sigma(Y)$, where $\{\mathcal{F}_t^{\Phi}\}$ describes the internal history of Φ , and Y (generating $\mathcal{F}_0$) is a nonnegative random variable with finite expectation. The cumulated $(P, \mathcal{F}_t)$ -stochastic intensity $\bar{\nu}(t)$ of (T_n) is assumed to be given by $\bar{\nu}(t) = Y \cdot \eta(t)$, where $\eta(t)$ is a deterministic function with derivative $\xi(t) \geq 0$. Hence, given the outcome $Y = y$ the random variable $\Phi(t)$ is Poisson distributed with mean $y \cdot \eta(t)$. And the unconditional distribution of $\Phi(t)$ is given by

$$\begin{aligned} P(\Phi(t) = k) &= E \left[\frac{[Y\eta(t)]^k}{k!} \exp(-Y\eta(t)) \right], \\ k &= 0, 1, \dots \end{aligned} \quad (5)$$

The sequence T_n is called a $(P, \mathcal{F}_t)$ -doubly stochastic Poisson process. Both, the deterministic function η and the distribution of Y can be specified. For instance, if $\eta(t) = t$ then T_n is called a *mixed Poisson process*, and if $P(Y = y_0) = 1$ the sequence (T_n) represents a *non homogeneous Poisson process* with the deterministic intensity function $y_0 \cdot \xi(t)$.

The following types belong to the most common models for η :

1. Weibull type: $\eta(t) = t^{\alpha+1}$ ($\alpha > -1$)
2. log-linear type: $\eta(t) = t \cdot e^{\alpha t^\gamma}$ ($\alpha \geq 0$, $\gamma \geq 0$)
3. logistic type: $\eta(t) = t \cdot [1 + \ln(1 + \alpha t^\gamma)]$ ($\alpha \geq 0$, $\gamma > -1$).

The random variable Y is a frailty variable. The notion of frailty provides a convenient way to introduce random effects, association, and unobserved heterogeneity into models for survival data. In its simplest form, a frailty is an unobserved random proportionality factor that modifies the hazard function of an individual, or of related individuals. Y can be specified too.

Let us now consider a marking of the sequence T_n [15]. At every time point T_n , a shock causes a random degradation. We describe the degradation increment at T_n by the mark X_n . Let $(\mathbf{R}^+, \mathcal{B}^+)$ be the space of marks and let G be a stochastic kernel from $(\mathbf{R}^+, \mathcal{B}^+)$ to $(\mathbf{R}^+, \mathcal{B}^+)$. Then $\Phi = (T_n, X_n)$ is said to be a *position-dependent G-marking* of T_n if $X_1, X_2, \dots$ are conditionally independent given T_n where for all $B \in \mathcal{B}^+$ and $n \in \mathbf{N}$ the following relation holds true:

$$\begin{aligned} P(X_n \in B | (T_n)) &= G(T_n, B) \\ P - a.s. \quad \text{on } \{T_n < \infty\}. \end{aligned} \quad (6)$$

Moreover, we assume that each mark X_n and Y are conditionally independent given (T_n) , that is, $P(X_n \in B | (T_n), Y) = P(X_n \in B | (T_n))$. With a position-dependent marking, it is possible to describe a degradation model where the increment at the n th shock depends on the time T_n of the n th shock.

For example, let U_n be a sequence of nonnegative iid random variables with the density f_U and let $\delta \in \mathbf{R}$. We assume that

the sequence U_n is independent of T_n . The sequence X_n is defined by $X_n = U_n \cdot e^{\delta T_n}$. That means, we get degradation increments which tend to be increasing ($\delta > 0$) or decreasing ($\delta < 0$). The stochastic kernel G is given by

$$\begin{aligned} G(t, B) &= \int_B f_U(x \cdot e^{-\delta t}) \cdot e^{-\delta t} dx, \\ B &\in \mathcal{B}^+, \quad t \geq 0. \end{aligned}$$

For $\delta = 0$, we have the special case of independent marking. In this case, G defines a probability measure which is independent on the time t .

Characteristics of the Degradation Process

In the section titled “Modeling Degradation by Marked Point Processes,” we introduced a position-dependent marking of a $(P, \mathcal{F}_t)$ -doubly stochastic Poisson process where the filtration $\{\mathcal{F}_t\}$ is given by $\mathcal{F}_t = \mathcal{F}_t^\Phi \vee \sigma(Y)$.

Then from Ref. 15, $\Phi = (T_n, X_n)$ has the $(P, \mathcal{F}_t)$ -stochastic intensity kernel

$$\lambda(t, B) = Y \xi(t) G(t, B), \quad B \in \mathcal{B}^+,$$

where

$$\begin{aligned} \lambda(t+, B) &= \lim_{s \rightarrow 0+} \frac{1}{s} \cdot E \left[\sum_{n=1}^{\infty} I(t < T_n \leq t + s, \right. \\ &\quad \left. X_n \in B) \middle| \mathcal{F}_t \right], \quad B \in \mathcal{B}^+. \end{aligned}$$

But usually, Y cannot be observed such that the actual available information does not coincide with the filtration $\{\mathcal{F}_t\}$. In some cases, as for applying the maximum likelihood theory, we have to consider the intensity kernels with respect to the observed filtration. For example, the $(P, \mathcal{F}_t^\Phi)$ -stochastic intensity kernel of Φ has the representation

$$\begin{aligned} \tilde{\lambda}(t, B) &= E[\lambda(t, B) | \mathcal{F}_{t-}^\Phi] \\ &= \xi(t) G(t, B) E[Y | \mathcal{F}_{t-}^\Phi], \quad B \in \mathcal{B}^+, \end{aligned}$$

with

$$E[Y | \mathcal{F}_{t-}^\Phi] = \frac{\int_0^\infty y^{\Phi(t-)+1} e^{-y \eta(t)} F_Y(dy)}{\int_0^\infty y^{\Phi(t-)} e^{-y \eta(t)} F_Y(dy)},$$

where F_Y denotes the distribution function of Y .

We want to present some characteristics of the counting process $(\Phi(t))$, the sequence of marks (X_n) , the degradation process (Z_t) , as well as the first passage time (Z^h) .

The Counting Process $\Phi(t)$. Frequently, the expected number of shocks up to any time t and other moments of $\Phi(t)$ are of interest. According to Equation (5), we can express the k th ordinary and central moments of $\Phi(t)$ as linear combinations of moments of Y multiplied by powers of the deterministic function $\eta(t)$.

Actually, let $S(k, u)$ denote the Stirling numbers of the second kind where $S(k, u)$ can be recursively determined

$$S(k, u) = S(k-1, u-1) + u \cdot S(k-1, u), \\ 1 \leq u \leq k, \quad (S(0, 0) := 1, S(0, u) = 0).$$

We make use of

$$n^k = \sum_{u=1}^k S(k, u) n(n-1) \times \cdots \times (n-u+1)$$

and we consider the factorial moments of a Poisson-distributed random variable with mean $y \eta(t)$. Some elementary calculations yield

$$E[\Phi(t)^k] = \int_0^\infty \sum_{n=0}^\infty n^k \frac{[y \eta(t)]^n}{n!} e^{-y \eta(t)} dF_Y(y) \\ = \sum_{u=1}^k S(k, u) \cdot E[Y^u] \cdot \eta(t)^u. \quad (7)$$

In particular, we find

$$\begin{aligned} E[\Phi(t)] &= E[Y] \eta(t) \\ \mu_2(\Phi(t)) &= \text{Var}(\Phi(t)) = E[Y] \eta(t) \\ &\quad + \text{Var}(Y) \eta(t)^2 \\ \mu_3(\Phi(t)) &= E[Y] \eta(t) + 3 \text{Var}(Y) \eta(t)^2 \\ &\quad + \mu_3(Y) \eta(t)^3 \\ \mu_4(\Phi(t)) &= E[Y] \eta(t) + (4 \text{Var}(Y) + 3E[Y^2]) \\ &\quad \times \eta(t)^2 + (6E[Y^3] - 12E[Y^2]E[Y] \\ &\quad + 6E[Y]^3) \eta(t)^3 + \mu_4(Y) \eta(t)^4, \quad (8) \end{aligned}$$

where $\mu_k(\cdot)$ denotes the k th central moment of a random variable.

The Sequence (X_n) and the Degradation Process (Z_t) . In the considered case of a position-dependent marking the size of the n th degradation increment depends on the time T_n of the n th shock. Using Equation (6), the distribution of the n th mark X_n is given by

$$P(X_n \in B) = E[G(T_n, B)] \\ = \int_0^\infty G(t, B) f_{T_n}(t) dt, \quad (9)$$

where the density f_{T_n} of T_n has the representation

$$f_{T_n}(t) = \frac{d}{dt} P(\Phi(t) \geq n) \\ = n \cdot \frac{\xi(t)}{\eta(t)} \cdot P(\Phi(t) = n), \quad n \geq 1.$$

As we can see from Equation (9), it is often difficult or strenuous to determine the distribution and the expectation of X_n , respectively. Frequently, we are more interested in the expected cumulative degradation at any time t . In order to simplify notations, we deal with continuous marks X_n . Let $g(T_n, x)$ denote the conditional density of X_n where $g(t, x)$ is given by $g(t, x) = \frac{\partial}{\partial x} G(t, [0, x])$.

Theorem 1. Let $\Phi = ((T_n, X_n))$ be a position-dependent marking of a doubly

stochastic Poisson process with the stochastic intensity kernel

$$\lambda(t, B) = Y \cdot \xi(t) G(t, B), \quad B \in \mathcal{B}^+.$$

Then the expectation of the cumulative degradation at time t is given as

$$E[Z(t)] = E[Y] \int_0^t \xi(s) \cdot \int_0^\infty x \cdot g(s, x) dx ds, \quad t \in \mathbf{R}^+. \quad (10)$$

Sketch of the proof.

By the definition of an intensity, it may be shown that

$$E \left[\sum_{n=1}^{\Phi(t)} \psi(T_n) \right] = E[Y] \int_0^t \psi(s) \xi(s) ds, \quad t \in \mathbf{R}^+$$

for any measurable function ψ . Further, we can express the expectation $E[Z(t)]$ as

$$E[Z(t)] = E \left[\sum_{n=1}^{\Phi(t)} \int_0^\infty x g(T_n, x) dx \right],$$

such that Equation (10) immediately follows.

Let us mention that in the special case of an independent marking, we get the well-known result $E[Z(t)] = E[\Phi(t)] \cdot E[X_1]$. Generally, the expectation $E[Z(t)]$ depends on both, the shape of the deterministic functions η , ξ , and the kernel G .

The Cumulative Degradation at Time t and the First Passage Time Z^h . Another problem is to find the distribution of the cumulative degradation $Z(t)$ at time t . It is easy to see that the distribution can be calculated by

$$P(Z(t) \leq u) = I(0 \leq u)P(\Phi(t) = 0) + \sum_{n=1}^{\infty} P(X_1 + \dots + X_n \leq u, \Phi(t) = n).$$

In the case of independent marking, we get the more simple equation

$$P(Z(t) \leq u) = I(0 \leq u)P(\Phi(t) = 0) + \sum_{n=1}^{\infty} G^{*(n)}(u) \cdot P(\Phi(t) = n), \quad (11)$$

where G is the distribution function of any mark and $G^{*(n)}$ represents the n th convolution of G . The calculation of this distribution is difficult even in the case of independent marking. Methods for calculating the degradation distribution for special distributions of marks can be found in Ref. 21. Explicit expressions for this distribution are known mostly for simple models.

We defined the first passage time Z^h for any state of first X_0 at time $T_0 := 0$ and a random level $h - X_0$ respectively, that is,

$$Z^h = \inf \left\{ t : \sum_{n=0}^{\infty} I(T_n \leq t) \cdot X_n \geq h \right\} = \inf \left\{ t : Z(t) \geq h - X_0 \right\}.$$

If X_0 is deterministic and if it is possible to calculate the degradation distribution then with that, the distribution of the first passage time is also given. Here, we use the relation

$$P(Z^h > t) = P(Z(t) < h - X_0). \quad (12)$$

Special examples as well as parameter estimates for these models can be found in Refs 34–36.

DANTZIG–WOLFE DECOMPOSITION

WILLIAM CHUNG
Department of Management
Sciences, City University of
Hong Kong, Hong Kong

DANTZIG–WOLFE DECOMPOSITION METHOD

Consider the following linear programming (LP) problem:

Block-Angular Linear Programming (BALP)

$$\begin{aligned} \text{Min}_{x_1, \dots, x_m} \quad & c_1^T x_1 + c_2^T x_2 + \dots + c_m^T x_m \\ \text{s.t.} \quad & L_1 x_1 + L_2 x_2 + \dots + L_m x_m \geq h \quad (\beta) \\ & B_1 x_1 \geq b_1 \quad (\pi_{S1}) \\ & B_2 x_2 \geq b_2 \quad (\pi_{S2}) \\ & \vdots \\ & B_m x_m \geq b_m \quad (\pi_{Sm}) \\ & x_j \in R_+^{n_j} \text{ for } j = 1, \dots, m, \end{aligned}$$

where all vectors are column vectors and the superscript T indicates the transpose of a vector or matrix. The vectors c_j, h , and b_j and the matrices L_j and B_j have appropriate dimensions. $\sum_{j=1}^m L_j x_j \geq h$ represents the *linking constraints* (also known as *coupling constraints* or *global constraints*), and $B_j x_j \geq b_j$ is the *block constraints* (or *local constraints*). β and π_{S_j} are the dual price vectors of the linking constraints and the block constraints, respectively. The linking constraints involving variables from different blocks drastically complicate the solution of the problem and prevent its solution by blocks. In order to improve computational efficiency by exploiting the sparsity and the special structure of the BALP, Dantzig and Wolfe [1,2] devised the first decomposition

method to decompose the large-scale BALP into m small subproblems (SPs) and a so-called *master problem*. Applying the corresponding decomposition algorithm, the SP and the master problem are to be solved iteratively until the solution to the BALP is found.

The main idea of the Dantzig–Wolfe (DW) decomposition method is to relax the linking constraints from the BALP and consider them at a superordinate level in the master problem. The resulting problem can be decomposed into m small SPs and is often solved more efficiently than BALP. It is worth mentioning that if $m = 1$ and the resulting problem has a special structure such as a network structure, the computation of the SP solution might be very efficient.

Minkowski's Representation Theorem

Define the polyhedron of local constraints by $S_j = \{x_j | x_j \geq 0, B_j x_j \geq b_j\}$. Let $X_j^{\bar{P}_j} = (x_j^1, x_j^2, \dots, x_j^{\bar{P}_j})$ and $X_{rj}^{\bar{R}_j} = (r_j^1, r_j^2, \dots, r_j^{\bar{R}_j})$ denote the matrix of all the extreme points and extreme rays in S_j , respectively. Hence, the superscripts $\bar{P}_j$ and $\bar{R}_j$ indicate the number of extreme points and extreme rays in S_j , respectively. That is, $X_j^{\bar{P}_j}$ and $X_{rj}^{\bar{R}_j}$ consist of $\bar{P}_j$ and $\bar{R}_j$ columns, respectively. Through Minkowski's Representation Theorem [3], we can show that any point $\hat{x}_j$ in S_j may be expressed as a convex combination of its extreme points plus a nonnegative combination of the extreme rays. That is,

$$\hat{x}_j = X_j^{\bar{P}_j} \lambda_j^{\bar{P}_j} + X_{rj}^{\bar{R}_j} \delta_j^{\bar{R}_j}, \text{ with}$$

$$\sum_{p=1}^{\bar{P}_j} \hat{\lambda}_j^p = 1, \hat{\lambda}_j^p \geq 0, \hat{\delta}_j^r \geq 0,$$

$$p = 1, \dots, \bar{P}_j, r = 1, \dots, \bar{R}_j,$$

where $\lambda_j^{\bar{P}_j} = (\hat{\lambda}_j^1, \dots, \hat{\lambda}_j^{\bar{P}_j})^T$ and $\delta_j^{\bar{R}_j} = (\hat{\delta}_j^1, \dots, \hat{\delta}_j^{\bar{R}_j})^T$.

Reformulation

Using the Minkowski's Representation Theorem, the BALP can be reformulated into the following equivalent problem, the so-called *full master problem*:

$$\begin{aligned}
& \text{Min}_{\substack{\bar{P}_j, \bar{R}_j \\ \lambda_j^j, \delta_j^j}} \sum_{j=1}^m c_j^T \left(X_j^{\bar{P}_j} \lambda_j^{\bar{P}_j} + X_{r_j}^{\bar{R}_j} \delta_j^{\bar{R}_j} \right) \\
& \text{s.t.} \sum_{j=1}^m L_j \left(X_j^{\bar{P}_j} \lambda_j^{\bar{P}_j} + X_{r_j}^{\bar{R}_j} \delta_j^{\bar{R}_j} \right) \geq h \quad (\beta) \\
& e^{\bar{P}_j^T} \lambda_j^{\bar{P}_j} = 1 \quad (\pi_j) \\
& \text{for } j = 1, \dots, m \\
& \text{all } \lambda_j^{\bar{P}_j} \geq 0, \delta_j^{\bar{R}_j} \geq 0,
\end{aligned}$$

where $e^{\bar{P}_j} = (1, 1, \dots, 1)^T$, the unit $\bar{P}_j$ -vector, and π_j is the dual price value corresponding to the j th convexity constraint $e^{\bar{P}_j^T} \lambda_j^{\bar{P}_j} = 1$.

The Decomposition Algorithm

It is not necessary to write the complete specification of the *full master problem* in advance because the *full master problem* could have a great many variables. Rather, the columns of the *full master problem* should be generated as they are needed. Following is a discussion of the mechanism for generating these columns.

Consider iteration k of the algorithm and suppose a subset of the extreme points, P_j columns, and the extreme rays, R_j columns, has been generated. Obviously, $P_j + R_j < \bar{P}_j + \bar{R}_j$. Thus, the matrices of the extreme points and rays become $X_j^{P_j}$ and $X_{r_j}^{R_j}$, respectively. With these matrices, what is called a *restricted master program* (RMP) is solved, representing an approximation to the original BALP (or the full master problem):

$$\begin{aligned}
& [\text{RMP}^k] \\
& \text{Min}_{\substack{P_j, R_j \\ \lambda_j^j, \delta_j^j}} \sum_{j=1}^m c_j^T \left(X_j^{P_j} \lambda_j^{P_j} + X_{r_j}^{R_j} \delta_j^{R_j} \right)
\end{aligned}$$

$$\begin{aligned}
& \text{s.t.} \sum_{j=1}^m L_j \left(X_j^{P_j} \lambda_j^{P_j} + X_{r_j}^{R_j} \delta_j^{R_j} \right) \geq h \quad (\beta^k) \\
& e^{P_j^T} \lambda_j^{P_j} = 1 \quad (\pi_j^k) \\
& \text{for } j = 1, \dots, m \\
& \text{all } \lambda_j^{P_j} \geq 0, \delta_j^{R_j} \geq 0,
\end{aligned}$$

where β^k and π_j^k are the dual prices of the corresponding constraints at iteration k .

Note that the adjective “*restricted*” refers to the fact that the RMP ^{k} does not contain all extreme points and rays in S_j , but only the subset of extreme points and rays.

Consider the dual problem of the RMP ^{k} , we have

$$\begin{aligned}
& \text{Max}_{\beta^k, \pi_j^k} \beta^k h + \pi_1^k + \pi_2^k + \dots + \pi_j^k \\
& \text{s.t.} \quad \beta^k L_j X_j^{P_j} + \pi_j^k \leq c_j^T X_j^{P_j} \\
& \quad \text{for } j = 1, 2, \dots, m \\
& \quad \beta^k L_j X_{r_j}^{R_j} \leq c_j^T X_{r_j}^{R_j} \\
& \quad \text{for } j = 1, 2, \dots, m \\
& \quad \beta^k \geq 0,
\end{aligned}$$

Assume that we find the optimal solutions for the RMP ^{k} , and, β^k and π_j^k are the associated optimal solution to the dual problem. It is easily shown that if $\beta^k L_j x_j + \pi_j^k \leq c_j^T x_j$ and $\beta^k L_j r_j \leq c_j^T r_j$ for all x_j and r_j in S_j respectively, then the convex combinations of $X_j^{P_j}$ and $X_{r_j}^{R_j}$ are optimal in the original problem, BALP. It also implies that no other negative reduced costs column exists for improving the RMP ^{k} . However, if there exists a vector x_j^{k+1} (or r_j^{k+1}) in S_j for any j , such that

$$\begin{aligned}
& \beta^k L_j x_j^{k+1} + \pi_j^k > c_j^T x_j^{k+1} \\
& \beta^k L_j r_j^{k+1} > c_j^T r_j^{k+1}; \quad \text{i.e.,} \\
& c_j^T x_j^{k+1} - \beta^k L_j x_j^{k+1} - \pi_j^k < 0 \\
& c_j^T r_j^{k+1} - \beta^k L_j r_j^{k+1} < 0,
\end{aligned}$$

then adding this new point to the RMP^k may result in an improved solution. To determine whether such x_j^{k+1} (or r_j^{k+1}) exists in S_j , for each j we need to solve the SP.

$$\text{SUB}_j^k : \text{Min}_{x_j \in S_j} (c_j^T - \beta^{k-1T} L_j) x_j.$$

Let $x_{S_j}^k$ (or $r_{S_j}^k$ if SUB_j^k is unbounded) be the solution of the SUB_j^k . If SUB_j^k is unbounded, an extreme ray, $r_{S_j}^k$, with $c_j^T r_{S_j}^k - \beta^{k-1T} (L_j r_{S_j}^k) < 0$ is to be found as a dual extreme ray. For any j , if $c_j^T x_{S_j}^k - \beta^{k-1T} (L_j x_{S_j}^k) - \pi_j^{k-1} < 0$ (or $c_j^T r_{S_j}^k - \beta^{k-1T} (L_j r_{S_j}^k) < 0$ if SUB_j^k is unbounded), then the corresponding $x_{S_j}^k$ (or $r_{S_j}^k$) can be a new *proposal* column x_j^{k+1} (or r_j^{k+1}) to be added to the matrices $X_j^{P_j}$ (or $X_{r_j}^{R_j}$) in the “next” RMP^k , for an improved solution. Therefore, the columns of the full master problem are generated as they are needed. For details, the reader is directed to the article on column generation (see **Column Generation**).

Now we state the *DW decomposition algorithm*: A “null matrix” is a “matrix” with no columns.

Step 0. Set $k = 0$. Choose $\beta^0 = 0$ and $P_j = R_j = 0$. Set X_j^0 and $X_{r_j}^0$ to the null matrix, $j = 1, 2, \dots, m$.

Step 1. Increment $k \leftarrow k + 1$. Solve all the SUB_j^k .

Step 1.1. If $k = 1$ and any of the SUB_j^k is infeasible, then STOP: the original problem is infeasible; otherwise, go to Step 2.

Step 1.2. If $k > 1$ and for any j ,

$$\begin{aligned} & c_j^T x_{S_j}^k - \beta^{k-1T} (L_j x_{S_j}^k) - \pi_j^{k-1} < 0 \\ & \text{(or } c_j^T r_{S_j}^k - \beta^{k-1T} (L_j r_{S_j}^k) < 0 \text{ if } \text{SUB}_j^k \\ & \text{is unbounded),} \end{aligned}$$

go to Step 2; otherwise, STOP: the solution of RMP^{k-1} is an optimal solution.

Step 2. $P_j \leftarrow P_j + 1$ and place the solution $x_{S_j}^k$ in the matrices $X_j^{P_j} = [X_j^{P_j-1}, x_{S_j}^k]$ (or $R_j \leftarrow R_j + 1$ and place $r_{S_j}^k$ in $X_{r_j}^{R_j} = [X_{r_j}^{R_j-1}, r_{S_j}^k]$ if SUB_j^k is unbounded); and go to Step 3.

Step 3. Solve RMP^k . Record β^k, π_j^k . Go back to Step 1.

Initialization

The decomposition algorithm can be started with an initial set of proposals that can be found in Step 0 and Step 1.1. If for any of the SPs, SUB_j^1 is infeasible, then the original problem is infeasible. Otherwise, we can use these optimal values $x_{S_j}^1$ (or rays $r_{S_j}^1$) to generate an initial set of proposals to be used in the RMP [2,4].

However, the initial proposals may violate the linking constraints in the RMP^k . We can start solving the RMP^k using the same device employed for the general LP problem, called the *Phase One*. We formulate the following Phase-One RMP^k by introducing artificial variables and minimizing them.

$$\begin{aligned} & \text{Min}_{x_a} e^{\dim x_a^T} x_a \\ & \text{s.t. } \sum_{j=1}^m L_j (X_j^{P_j} \lambda_j^{P_j} + X_{r_j}^{R_j} \delta_j^{R_j}) + x_a \geq h \quad (\beta^k) \\ & e_j^{P_j^T} \lambda_j^{P_j} = 1 \quad (\pi_j^k) \quad \text{for } j = 1, 2, \dots, m \\ & \lambda_j^{P_j} \geq 0; \delta_j^{R_j} \geq 0 \quad \text{for } j = 1, 2, \dots, m \\ & x_a \geq 0. \end{aligned}$$

We also have the corresponding *Phase-One* $\text{Sub}_j^k : \text{Min}_{x_j \in S_j} (-\beta^{kT} L_j) x_j$. After using the DW decomposition algorithm to solve the Phase-One problem, we either have (i) $e^{\dim x_a^T} x_a > 0$, indicating that the original problem has no feasible solution, or (ii) $e^{\dim x_a^T} x_a = 0$, indicating that we have a set of proposals for which there is a convex combination that is feasible in the linking constraints, to start the decomposition.

On the other hand, we may use the “big M” method: artificial variables with large cost

coefficients (M) are added in each linking constraint of the RMP^k , like the one in *Phase-One RMP^k* . The corresponding objective function becomes $\sum_{j=1}^m c_j^T (X_j^{P_j} \lambda_j^{P_j} + X_{r_j}^{R_j} \delta_j^{R_j}) + M \times x_a$, and the constraint $x_a \geq 0$ is to be added.

Finite Convergence

The decomposition algorithm terminates in a finite number of iterations, yielding a solution of the original problem (assuming it is a non-degeneracy case). At each iteration, the SUB_j^k provides extreme points $x_{S_j}^k$ (or extreme rays $r_{S_j}^k$) as proposals to the RMP^k . Since the SP is a LP model that consists of a finite number of extreme points and rays, the algorithm converges in a finite number of iterations. Moreover, the stopping condition indicates that there is no new proposal (extreme point or extreme ray) improving the original problem. See Ref. 2 for details.

THE MYTH OF COMPUTATIONAL EFFICIENCY

Apart from its theoretical elegance, it was believed that the DW decomposition algorithm held great promise for large-structured LPs, where for instance, the SP may be further decomposed into much smaller SPs according to its special structure, similar to the block-angular one. However, early attempts at implementation and application were generally not encouraging.

Beale *et al.* [5] reported the first practical application of DW decomposition to an oil field–operation problem. The algorithm was implemented as an internal extension to the commercial LP/90/94 mathematical programming software. The software had a theoretical capacity of 100 blocks, 100,000 constraints in total, 1000 constraints in any block, and an unlimited number of variables. Mainly, the DW method did not perform better than the rival simplex method.

A number of practical experiences were summarized in Ref. 6. Based on the selected studies' documents, for instance [4,7–9], generally, the greater the number of proposals used to initialize the algorithm, the faster the solution can be found. However, the DW

method is time consuming and converges slowly toward an optimal solution. Hence, the DW method's primary advantage may be when it is the only algorithmic choice for a problem that is too large to be solved in one piece.

Long-Tail Convergence

Dirickx and Jennergren [6] also summarized that the algorithm is prone to rapid initial convergence but “tails off” upon approaching optimality, that is, while a near optimal solution is usually approached considerably fast, only little progress per iteration is made close to the optimum. Consequently, time-savings from the rapid initial convergence tend to be offset by the number of the tail-off cycles required. This phenomenon is called the *tailing-off effect* or *long-tail convergence*.

There is an intuitive assessment of this phenomenon; however, a theoretical understanding has been only partly achieved. Adler and Ülkücü [10] used combinatorial arguments to explain this tail-off behavior. They used the concept of diameter of polytopes, which is the maximal number of affinely independent points contained in a polytope. Obviously, the diameter is a monotone increasing function of the number of extreme points. Hence, they argued that the number of simplex steps might be proportional to the diameter of the polytope defining the feasible region. Since it is well known that the decomposition algorithm is essentially the simplex method applied to the MP (master program), it is expected to have many more cycles than simplex iterations required for the original problem.

Nazareth [11] used a set of LP problem examples consisting of a few constraints and variables to identify the numerical difficulties that can generally occur when applying the DW method. Nazareth showed that even when stable techniques such as a stable refactorization of the corresponding basis matrix are employed, the columns of the computed MP could differ substantially from those of the true one. Moreover, it is shown that errors in the extreme points (or rays) defining the columns of the computed master can be correlated with errors in solutions obtained from this computed master, thus perturbing the

optimal solution. Hence, this optimal solution must be relatively insensitive to perturbations of the initial data. Later, Nazareth [12] noted that because of the changes of primal and dual variables are applied iteratively, a certain amount of “cleaning up” is to be expected. Kim and Nazareth [13] discussed that finding an appropriate convex combination of existing proposals might be held back by the possible “complex combinatorial structure” of the faces of the polyhedron defined by the SPs.

While the question of numerical stability was first discussed by Nazareth [11], although not in the context of convergence, Ho [14] explained that the implicit error bounds might imply a tolerance for convergence below which further apparent improvements should be considered as noise. As the exact error analysis for this kind of algorithm is impossible, the most promising approach for further investigating this question is to conduct controlled experiments using various degrees of numerical accuracy in the arithmetic and comparing the resulting convergence behavior. If inaccuracy causes (at least in part) long convergence or nonconvergence, then specific techniques for improvement may be designed. In Ref. 14, certain procedures based on the method of iterative refinement are proposed. However, as pointed out earlier, what the decomposition approach needs is a way to clean-up the data periodically, that is, an analogy to basis reversion for the revised simplex method.

However, Lübbecke and Desrosiers [15] remarked that tailing-off also occurs when columns are computed exactly (e.g., by use of combinatorial algorithms).

Swoveland [16] suggested a modification of the column-generation operation in the DW decomposition. Instead of the usual procedure of solving one or more SPs at each iteration, it is shown how the SPs may be solved parametrically to minimize the immediate improvement in the objective’s value in the MP, rather than to minimize the reduced cost of the entering column. It is hoped that in some cases, the use of the suggested procedure may improve the slow rates of convergence common in decomposition algorithms.

Column Dropping

One may consider that column dropping from the MP would improve computational efficiency. Dantzig [17] described three strategies for deciding how long proposals should persist in the MP: retain all proposals; delete all nonbasic proposals immediately (apart from those just generated); or keep all proposals until a certain proposal capacity is reached, and then purge the proposal with the worst reduced cost. The question of when to delete proposals from the MP is not entirely clear. Beale *et al.* [5] chose the first option. The best reported result for a problem found that the DW method performed marginally better than the rival simplex method. For *nonlinear programming (NLP)*, Murphy [18] provided two conditions under which columns may be dropped from the restricted master. However, the computational results of [19] showed virtually no difference in the measures of computational efficiency when all columns are retained and when only basic columns are retained.

BOUNDS ON THE OPTIMAL SOLUTION VALUE

The tail-off convergence behavior indicates that the number of iterations needed to solve the problem by the DW method could be much larger than the number required by an application of the ordinary simplex method. Hence, it may be desirable to terminate before optimality is reached. Indeed, providing bounds on the optimal solution value is one of the attractive features of the DW method.

Let z^* be the optimal solution value of the original problem. Suppose that at iteration k , one or more of the SUB_j^k have unbounded optimal solutions, then no bound on z^* can be obtained. However, if all SUB_j^k have bounded optimal solutions, we can have $z_M^k = \beta^{kT} h + \sum_{j=1}^m \pi_j^k$ to be the optimal solution value of the “restricted” MP. Obviously, for the minimization problem, $z^* \leq z_M^k$. On the other hand, from the results of the SUB_j^k ’s dual solution, we have $\pi_{Sj}^{kT} B_j + \beta^{k-1T} L_j \leq c_j^T$

which provides the dual feasible solution $(\pi_{S_j}^k, \beta^{k-1})$ to the original BALP. Hence, we have $\beta^{k-1^T} h + \sum_{j=1}^m \pi_{S_j}^{kT} b_j \leq z^*$. Let $z_S^k = \sum_{j=1}^m \pi_{S_j}^{kT} b_j - \pi_j^{k-1} = \sum_{j=1}^m c_j^T x_{S_j}^k - \beta^{k-1^T} (L_j x_{S_j}^k) - \pi_j^{k-1}$, and we get $z_M^k + z_S^k \leq z^* \leq z_M^k$, which may be used to construct a simple stopping rule: terminate the algorithm if the gap between bounds is smaller than the preset tolerance constant.

ADVANCED IMPLEMENTATION FOR COMPUTATIONAL EFFICIENCY

One may consider that a more advanced implementation may enhance the computational efficiency of the DW method. However, the results of Refs 20 and 21 resubstantiated that it was unlikely for the DW method to be significantly more efficient than the simplex approach, whenever the latter can produce a solution at an acceptable cost. Hence, the DW method should be used as a modeling approach, similar to its application in Ref. 22, rather than simply as a solution tool.

Ho [23] provided more computational results on a diverse collection of problems from real applications in order to clarify the tailing-off convergence phenomenon. A *relative primal-dual gap* of 0.1% (or smaller) was used for all cases as a stopping criterion, and it was observed that more iterations were expected if a much more stringent tolerance was used. However, most test problems required a surprisingly small number of iterations. Therefore, there is a question of whether these relatively low numbers of iterations observed were simply a result of suboptimality. In fact, there may not be any simple answer because of numerical error propagation. Ho also reported that the underlying numerical accuracy might not even guarantee a resolution of 0.1% in many situations. Moreover, such a tolerance is usually considered acceptable in practice.

Ho *et al.* [24] reported the results of their computational experience of the DW method implemented in *parallel* computers using the following decomposition strategies.

- A1. Start with RMP idle. Solve SUB_j, $j = 1, \dots, m$. SUB_j becomes idle when done. When all SUB_j are done, solve RMP with all S_j idle. Repeat until optimal.
- A2. With RMP idle, solve SUB_j, $j = 1, \dots, m$ until the first SUB_j is done with a new proposal. Solve RMP with all SUB_j idle. Repeat until optimal.
- A3. With RMP idle, solve SUB_j, $j = 1, \dots, m$ until the first proposal generation procedure is triggered by the first feasible solution $x_{S_j}^k$ to the SUB_j that satisfies $(c_j^T - \beta^{k-1^T} L_j) x_{S_j}^k - \pi_j^{k-1} < 0$. The corresponding proposal is generated [20]. Solve RMP with all SUB_j idle. Repeat until optimal.
- A4. With RMP idle, solve SUB_j, $j = 1, \dots, m$ until the first proposal. Continue SUB_j if not done while solving RMP. Whenever RMP is done, check for new proposals. Resolve. Whenever SUB_j is done, check for new prices from RMP. Resolve. Repeat until optimal.

While A1 optimizes all SPs, it was not necessarily true that it would converge fastest. The computational results showed that A2 increased the utilization of the processors, and the total run time was significantly inferior to the standard version (A1) in most of the cases tested. These results implied that A3 would be even less interesting. Hence, the only remaining option was A4. It was reported that the performance of A4 in keeping all the processors busy was improved.

RECENT COMPUTATIONAL EXPERIENCE

Gnanendran and Ho [25] investigated the strategies for improving efficiency in distributed DW decomposition by better balancing the load between the MP and SP processors. They reported computational experience on an Intel iPSC/2 hypercube multiprocessor with test problems having dimensions up to about 30,000 rows, 87,000 columns, and 200 coupling constraints. It was found that the parallel efficiency

of the distributed approach was critically dependent on the duration of the inherently serial master phase relative to that of the bottleneck SP. That is, the efficiency is bound by a factor that depends on the ratio of the duration of the master phase to the duration of the bottleneck SP. This ratio, in turn, is dependent on the number and “tightness” of the coupling constraints. Unlike speedup, which can often be improved by scaling the problem size in step with the number of processors, efficiency improvements must come about by better load balancing, such as through the partial overlapping of the MP and SP processes.

Rosen and Maier [26] implemented the DW method for a large-scale BALP in parallel, which was computationally tested on both a shared-memory vector multiprocessor (CRAY-2) and a local-memory hypercube (NCUBE/seven) with 64 processors. Computational results for problems with as many as 24,000 rows and 74,000 columns (1024 blocks and 1.4 million nonzero elements) were presented. A problem of this size was solved on the NCUBE in less than four minutes and the CRAY-2 in 37 s. Sundarraj *et al.* [27] applied DECUBE based on DECOMP to handle a power systems operations problem, which is a BALP with up to 37,200 rows, 120,000 columns, and 30 SPs. DECUBE written in Fortran employed the subroutines of DECOMP as building blocks which was a serial implementation of the DW method [20].

Tebboth [28] developed a parallel implementation of the DW method to solve problems up to 83,500 rows, 83,700 columns, and 622,000 nonzero elements. One instance of the problems was solved in 63% of the time taken by a commercial implementation of the simplex method.

The most recent application can be found in Ref. 29. With the planning horizon of a refinery ranging from 2–300 days, the problem consisted of up to 1 million constraints, 2.5 million variables, and 59 million nonzeros in the constraint matrix. Large instances became computationally challenging for generic state-of-the-art LP solvers, such as CPLEX. The computational results showed that the interior point algorithm and the block coordinate-descent

with a particular order of the variables were more effective than the DW method.

PRICE-DIRECTIVE DECOMPOSITION

From an economic viewpoint, the DW decomposition algorithm of the profit maximization problems can be interpreted as a process of price-directive coordination of the SPs, which are allowed to optimize their own objectives while vying for the shared resources. The MP plays the role of a coordinator who sets the prices (dual prices of the linking constraints), β^{k-1} , on the shared resources, h . Given such price levels, each SP seeks to optimize its own objective while “paying” for the consumption of shared resources. This process is the SP SUB $_j^k$, whose solution gives rise to a proposal (proposed consumption) $L_j x_j$. If the corresponding value of a stopping condition is positive, it signals to the coordinator that the proposal can be used to improve on the system-wide objective. After collecting all such profitable proposals from this round of coordination, the coordinator optimizes the system-wide objective over all available proposals. By taking convex combinations of proposals from each SP and requiring such combinations to satisfy the balance of shared resources, the coordinator can maintain system-wide feasibility while improving on the objective. This is the process involved in the “next” MP.

Optimal Allocation Model

Considering each sequence of MPs and SPs as a cycle in the coordinating process, equilibrium prices β^* on the shared resources will be obtained after a finite number of k iterations. At such prices, no SP will be able to generate a profitable proposal. The optimal activity levels for each SP are given by the convex combination of proposed solutions: $X_j^k \lambda_j^k$. This illustrates the well-known fact that decentralization cannot be accomplished by price direction alone. Generally, given only β^* , it is impossible for an SP to recover the optimal solution $X_j^k \lambda_j^k$ by itself. Nonetheless, having the SP activities dictated by the coordinator according to $X_j^k \lambda_j^k$ obviously detracts from the spirit of decentralized planning. Fortunately,

a better alternative exists. From the optimal restricted MP, the coordinator can compute the optimal allocation of the shared resources to each SP as $h_j^* = L_j X_j^k \lambda_j^k$. Given this allocation, each SP can then proceed to determine its own activities by solving the *Optimal Allocation Model* [30]:

$$\begin{aligned} & \text{SUB}_j^{k*} \\ & \text{Min}_{x_j} c_j^T x_j \\ & \text{s.t. } L_j x_j \geq h_j^* = h - \sum_{i \neq j} L_i X_i^k \lambda_i^k \\ & \quad B_j x_j \geq b \\ & \quad x_j \geq 0. \end{aligned}$$

This way, the SPs are accorded more procedural autonomy.

Optimal Degree of Decentralization

Since SPs can be aggregated, there is a choice in the degree of decentralization. Given a maximum of m SPs as in the aforementioned development, it is possible to decompose with anywhere from 1 to m SPs. Let us examine first the extreme case of using a single SP. There is a single convexity constraint in the MP. Moreover, the SP can still be decomposed and solved SP by SP as before, because their constraints do not interact. The only difference is that once the SP activities x_j are determined, an aggregate proposal $\sum_{j=1}^m L_j X_j^k$ is formed and submitted to the MP. This apparent decomposability of the aggregate SP may lead one to speculate that the formulations with 1 or m convexity constraints are equivalent. Extending the same argument to any other grouping of SPs implies that the number of convexity constraints is a direct measure of the degree of decentralization.

We can now address the question of what effect the degree of decentralization has on the process of price-directive resource allocation. Early literature [31,32, Chapter 3] was inconclusive mainly because of the emphasis on algorithmic performance and the lack of tools and models for significant empirical results.

Ho and Loute [30] reported some empirical results related to this issue. They focused

on the number of cycles required by the DW method as a measure of the amount of coordination necessary to achieve price-directive resource allocation. The results supported the general observation that the amount of coordination decreases with the increasing degree of decentralization, that is, the optimal degree of decentralization is the maximum number of SPs.

A Variant DW Method

Balas [33] developed an interesting infeasibility-pricing approach to apply the DW method by which the SPs were first solved. The infeasibility of the resulting solution for the linking program was used to generate a price-adjustment process (much like a market mechanism). This gradually corrected the objective functions of the SPs, until either some optimal solutions to the latter yielded a feasible solution to the MP (then the problem is solved), or evidence was obtained that the problem had no feasible solution.

ORGANIZATIONAL STUDIES

Following the economic viewpoint of price-directed coordination, the decomposition of mathematical programs have been developed extensively as models for organizational design and resource allocation in decentralized organizations [34–39]. Generally, we can conceptualize the allocation problem as a multilevel managerial coordination procedure, involving local (divisional) and global (organization-wide) resources, in which informational autonomy is to be maintained. That is, a coordination of resource usage by relatively autonomous divisions is to be effected in these models without any one agent in the organization accumulating complete knowledge of the technical resource transformations, payoffs or cost coefficients, and detailed plans that divisions utilize in converting resources to useful ends.

Empirical Investigation

Beside the above conceptual models, Christensen and Obel [40] conducted a simulation study about the coordination and

decentralized planning mechanism based on the DW decomposition algorithm. Almost at the same time, Moore [41] reported a laboratory empirical investigation into the implementation problems of applying the decomposition of mathematical programs in decentralized organizations. An example of the results was that high decision-time pressure would not worsen decision making.

Transfer Pricing

On the other hand, Burton *et al.* [42] studied the transfer pricing (or price coordination) in the context of the decentralized decision making process in the firm. They developed the analogy of the resource allocation versus transfer pricing through decomposition methods. Later, Burton and Obel [43] investigated the efficacy of price-and/or budget-planning approaches. They showed that for a changing environment, historical information (i.e., a past solution) was generally inferior to a combination of less precise information on current transfer prices, reasonable rules of thumb, and capacity constraints. However, more current information on prices and budgets yielded better plans. Further, they found that the transfer pricing yielded more nearly optimal plans in the first few iterations than a combination of prices and budgets, which in turn, was more efficient than budgets alone.

STAIRCASE LINEAR PROGRAMMING

Staircase-structured linear programs can naturally be found in the study of multi-period [44] and multistage problems, and can be formulated with the following basic structure.

$$\begin{aligned}
 & \text{Min}_{x_j \in R_j} c_1^T x_1 + c_2^T x_2 + \cdots + c_{m-1}^T x_{m-1} + c_m^T x_m \\
 & \text{s.t. } A_1 x_1 \geq b_1 \\
 & \quad B_1 x_1 + A_2 x_2 \geq b_2 \\
 & \quad \quad B_2 x_2 + A_3 x_3 \geq b_3 \\
 & \quad \quad \quad \vdots \\
 & \quad \quad \quad B_{m-1} x_{m-1} + A_m x_m \geq b_m \\
 & \quad x_j \in R_+^{n_j}.
 \end{aligned}$$

According to the DW terminology for block-angular systems, a multistage linear program is defined with linking variables that connect consecutive stages. Optimality conditions for the composite problem are partitioned into local and linking conditions. Hence, *nested decomposition* techniques apply the basic DW algorithm to a sequence of SPs, which were discussed in the last section of Ref. 1. That is, when the DW decomposition scheme is applied with the first stage as the master, the SP is also a multistage linear program with one stage less. The same decomposition is then applied to the SP, giving rise to a nested decomposition scheme in which each stage acts as an MP for the following stage and an SP for the preceding. Optimizing a single-stage problem implies that the corresponding “local” optimality conditions are satisfied. [45–48] further developed the DW algorithm for staircase LPs with more discussions on bounds, initialization, convergence, Phase-Two, and computational experience.

In spite of these efforts, the nested decomposition techniques inherited the computational inefficiency of the DW method.

NONLINEAR PROGRAMMING PROBLEMS

Since this chapter is used specifically to describe the DW method of LP, other related topics of the DW method are given briefly.

Concave Programs/NLP

Dantzig and Wolfe [2] mentioned that if the cost function $c_j^T x_j$ was replaced by the convex function $f_j(x_j)$, the decomposition algorithm would be unchanged, except that the SPs become $\text{Min}_{x_j \in S_j} [f_j(x_j) - \beta^k L_j x_j]$. In fact, the DW method for concave programs can be viewed as an inner linearization of the *RMP* followed by a relaxation (the SP). Holloway [49] presented an approach that allows selective inner linearization of functions and utilizes a generalized pricing problem. It allows considerable flexibility in the choice of functions to be approximated using inner linearization. Using the generalized pricing problem guarantees that strict improvement in the value of the objective function is

achieved at each iteration and provides a termination criterion that is both necessary and sufficient for optimality. A specialization of this procedure results in an algorithm that is a direct extension of the DW decomposition algorithm. Other extensions and modifications of the DW method in the context of non-LP can be found in Refs 50 and 51 for nonconvex programming, and in Ref. 52 for providing an additional column and cut in the MP.

DW and Simplicial Decomposition

Von Hohenbalken [53] presented a simplicial decomposition method for non-LP problems and mentioned that the simplicial decomposition method belongs to a class of decomposition methods in another sense, namely, those descending from the DW decomposition principle for linear programs. Patriksson [54, Chapter 9] brought the simplicial decomposition method closer to the DW method by dualizing linking constraints in the SP with prices provided by the MP. Their works showed the close relationship between the DW method and the simplicial decomposition method in LP and NLP problems. (see the section titled “Network flows” in this encyclopedia).

Mixed-Integer Program, Branch-and-Bound, Branch-and-Price

Holm and Tind [55] presented a method on how to generalize the DW method to integer programming. Regardless of the choice between the two main solution methods, branch-and-bound or cutting-plane, the price functions generated by these two methods are similar, both being polyhedral and concave. These price functions are used to evaluate the consumption of central resources and to penalize any attempts to violate the requirement that the result must be an integer. Wentges [56] developed a so-called *weighted DW decomposition* procedure to improve the quality of the dual prices of the linking constraints for linear mixed-integer programming. Barnhart *et al.* [57] discussed a branch-and-price method, in which the DW decomposition is used for bounding within a branch-and-bound method for specially structured

integer programs. Columns are generated for each node (of a branch-and-bound tree) at which an LP relaxation is solved.

After this generalized paper, a series of MIP applications has been reported.

DW for Variational Inequality Problems

Chung *et al.* [58] presented a DW decomposition algorithm for a class of equilibrium models, which integrate a price-dependent demand component with an LP supply component. This method allows for further decomposition of the supply side (e.g., by region or commodity). Existing demand–supply decomposition methods for economic equilibrium models, based on the cobweb algorithm, may fail to converge. They showed that the DW method converges in a finite number of iterations. Later, Chung *et al.* [59] developed a general procedure to extend any decomposition method for optimization models to multiregional equilibrium models and showed how to apply the procedure with the DW decomposition method. Fuller and Chung [60] modified and generalized the work of Chung *et al.* [58,59] to produce an extension of DW decomposition to a class of variational inequality problems (see the article on **Variational Inequalities** in this encyclopedia).

INTRODUCTION

With the advent of the computer, there has been a corresponding rise in our ability to acquire and store data [1,2]. In many cases, the challenge lies not in the collection of the data, but in making intelligent inferences about the data. For instance, in biology, the use of gene expression microarrays have allowed researchers to measure the expression level of thousands of genes at once. But these gene expression measurements are not useful unless it is possible to identify the important genes that characterize a given phenomenon [3]. Therefore, with this rise in the amount of data that is available for us, there is the commensurate challenge in converting it into usable information. The methods used to process this information fall under the general rubric of “data mining” [4].

The overall goal of data mining, and hence the approaches that will be covered in this article, is to process the data such that underlying relationships between either the data points or the measurements can be identified. These relationships essentially define hypotheses that can be tested with more targeted experiments [5,6]. Specifically, this short article will focus primarily upon one specific problem under the data mining umbrella, namely, classification. In classification, one seeks to utilize a small training

set, that is data that has been previously labeled as belonging to a certain class, in order to classify data whose class is unknown, that is to predict the class the data belongs to.

CLASSIFICATION APPROACHES

The problems of data classification is essentially one of dimensionality reduction [7]. In such a case, we seek to find a mapping f , which allows us to map $x \in R^m \rightarrow R^{m'}$ s.t. $m \gg m'$. In the case of data classification, the reduction is performed such that the data is reduced to a single dimension $m' = 1$, the class. This dimension then becomes the classification. For the purpose of consistency, we will define the data as a matrix X of dimension $m \times n$. In this representation, each row represents an individual data point, and each column represents an individual descriptor in the data. Therefore, each data point $x \in X \subseteq R^n$ can be treated as a point in n -dimensional space. Appropriate preprocessing of the data may be required to transform the data into this form. Although in many cases this transformation can be trivial, in other cases transforming the data into a “workable” form is a highly nontrivial task. The goal therefore is to estimate an explicit, or implicit, function that maps points of the feature vector from the input space $X \subseteq R^n$, to an output space C , given a finite sample. The concept of the finite sample is important because, in general, what we are given is a finite representative subset of the original space (training set) and we wish to make predictions on new elements of the set (testing set). The data mining tasks can thus be defined based on the nature of the mapping C and the extent to which the training set is characterized. If the predicted quantity is a categorical value, and if we know the value that corresponds to each element of the training set, then the question becomes how to identify the mapping that connects the feature vector and the corresponding categorical value (class). This problem is formally defined as the classification problem

(supervised learning). If the class assignment is not known and we seek to (i) identify whether a small, yet unknown, number of classes exist; (ii) define the mapping assigning the features to classes, then we have a clustering problem (unsupervised learning). A related problem associated with superfluous information in the feature vector is the so-called feature selection problem. This is a problem closely related to overfitting in regression. Having a minimal number of features, this leads to simpler models, better generalization, and easier interpretation. One of the fundamental issues in data mining is therefore, to identify the least number of features and subset of the original set of features that best address the two problems previously defined. The concept of parsimony (Occam's razor) is often invoked to bias the search [8]: never do with more what can be done with fewer. Although numerous methods exist for addressing these problems, they will not be reviewed here. Extensive articles of classification were recently presented in Refs 9 and 10.

Classification, and for that matter most of the data mining tasks, are fundamentally optimization problems. Mathematical programming methodologies formalize the problem definition and make use of recent advances in optimization theory and applications for the efficient solution of the corresponding formulations. In fact, mathematical programming approaches, particularly linear programming, have long been used in data mining tasks. The pioneering work of Mangasarian in Refs 11 and 12 demonstrated how to formulate the problem of constructing planes to separate linearly separable sets of points. In this summary, we will follow the formalism put forth in Ref. 13, since it presented one of the most comprehensive approaches to this problem. One of the major advantages of a formulation based on mathematical programming is the ease in incorporating explicit problem-specific constraints. This will be discussed in greater detail later in this summary.

As discussed earlier, the main goal in classification is to predict a categorical variable (class) based on the values of the feature vector. The general families of

methods for addressing this problem include the following [9]:

1. estimation of the conditional probability of observing class C , given the feature vector x ;
2. analysis of various proximity metrics and evaluation of the decision of class assignment based on proximity;
3. recursive input space partitioning to maximize a score of class purity (tree-based methods).

The three broad families which we will be covering are decision trees [14], support vector machines (SVMs) [15], and Bayes and nearest neighbor classifiers [16]. Decision trees represent an extension of the orthogonal partition such that rather than utilizing global partition planes, it is possible to utilize local partition planes. SVMs represent the use of arbitrary partition hyperplanes rather than orthogonal planes, and Bayesian classifiers utilize probabilistic measures rather than hard partitions.

Decision Trees

Decision trees represent a recursive partitioning of the feature space. Rather than utilizing a global partitioning of the feature space, a decision tree has a hierarchy of partitions. In lieu of a plane cutting through the entire data space, a decision tree partitions the space into a series of hyperrectangles [17]. The use of a recursive partitioning provides a method for one to take into account the inherent relationship between different features. By not treating the features as independent, it is possible to improve the accuracy of such a classifier. Aside from the increase in accuracy, one of the primary advantages of a decision tree over the other methods is the fact that they summarize the feature space in a concise and humanly interpretable manner.

A common algorithm for creating decision trees is C4.5 [18]. The algorithm first iterates through all of the different features and identifies the partition which most enriches a given class, as determined via a normalized information gain function [18], which

is given in Equation (1). The normalized gain function is essentially the application of entropy to determine the order that the partitions have imposed upon the training set. In Equation (1), a represents the attributes in a given feature, c represents the classes, and p represents the probability that a value lies within a given class. This information gain is then normalized via the denominator where S represents the splits at each level, and S_i represents how many objects are in each leaf node after a split. After the first partition has been created, the data set is recursively processed until the data set has been correctly classified. After the initial training set has been processed, the decision tree can then be used to classify unknown data points.

$$G = \frac{\sum_{i=1}^{a \in A+1} \sum_{j=1}^c -\frac{1}{p_j} \log\left(\frac{1}{p_j}\right) - \sum_{i=1}^a \sum_{j=1}^c -\frac{1}{p_j} \log\left(\frac{1}{p_j}\right)}{\sum_{i=1}^B -\frac{|S_i|}{|S|} \log \frac{|S_i|}{|S|}} \quad (1)$$

Support Vector Machines

The two-class classification problem can be formulated as the search of a function that assigns a given input vector x into two disjoint point sets A and B . The data are represented in the form of matrices. Assuming that the set A has m elements and the set B has k elements, then $A \in R^{m \times n}$, $B \in R^{k \times n}$, describe the two sets, respectively. The discrimination is based on the derivation of the hyperplane:

$$P = \{x|x \in R^n, x^T \omega = \gamma\}$$

with normal distance from the origin $\frac{|\gamma|}{\|\omega\|_2}$. The optimization problem then becomes determination of ω and γ such that the separating hyperplane P defines two open half spaces containing mostly points in A and B , respectively:

$$\begin{aligned} &\{x|x \in R^n, x^T \omega < \gamma\} \\ &\{x|x \in R^n, x^T \omega > \gamma\} \end{aligned}$$

Unless A and B are disjoint, the separation can only be satisfied within some error. Minimization of the average violation provides a possible approximation of the separating hyperplane [13]:

$$\min_{\omega, \gamma} \frac{1}{m} \|(-A\omega + e\gamma + e)_+\|_1 + \frac{1}{k} \|(-B\omega + e\gamma + e)_+\|_1$$

In Ref. 13, a number of linear programming reformulations are discussed; these explore the properties and structure of the optimization problem. In particular, an effective robust linear programming (RLP) reformulation was suggested, making possible the solution of large-scale problems:

$$\begin{aligned} \min_{\omega, \gamma, y, z} & \frac{e^T y}{m} + \frac{e^T z}{k} \\ \text{s.t.} & -A\omega + e\gamma + e \leq y \\ & -B\omega + e\gamma + e \leq z \\ & y, z \geq 0 \end{aligned}$$

In Ref. 19, it was further demonstrated how the aforementioned formulation can be applied repeatedly to produce complex space partitions similar to those obtained by the application of standard decision tree methods such as C4.5 [20] and CART [21].

SVMs were originally designed for binary classification. Extension to multiclass problems is still an open research area [22]. The earliest multiclass implementation is the one against all [23] by constructing k SVM models, where k is the number of classes. The i th SVM classifies the examples of class i against all the other samples in all other classes. Another alternative builds one classifier against another [24] by building $k(k-1)/2$ models where each is trained on data from two classes. The emphasis of current research is on novel methods for generating all the decision functions through the solution of a single, but much larger, optimization problem [22].

Bayes and Nearest Neighbor Classifiers

Probability-based methods are normally classification methods that utilize Bayes rule to calculate the probability that a given

data point will belong to one class versus another [25]. Thus, for every data point, we essentially calculate the probability $P(C_i|x_1, x_2, \dots, x_n)$, which is the conditional probability of a data point belonging to class C_i given its feature set x . In the most general implementation of Bayes rule, one implicitly assumes that each of the features can depend upon each other in terms of the overall classification. In this formulation, the use of the standard Bayesian rule can be thought of as a probabilistic implementation of an SVM, in which rather than having a separating hyperplane, one is placing different N-D probability distribution functions in the feature space. By looking at the intersection of the different probability distribution functions, one can calculate the probability by which a data point belongs within a certain class.

However, while the use of Bayes rule represents the most general form of probabilistic classification techniques, the most widely used technique is naïve Bayes, in which the Bayesian relationship $P(C_i|x_1, x_2, \dots, x_n)$, is approximated by $\forall i, \prod_{j=1}^n P(C_i|x_j)$ [26]. This simplification is based upon the assumption that the individual features are statistically independent; that is, that there are no relationships between the values of one feature versus another. The use of this second formulation is akin to the reduction of the SVM into the simpler partitioning scheme with orthogonal partition planes. The training of probability-based classifiers is a straightforward application of Bayes rule. Thus, in the general case, one will essentially calculate $P(C_i|x_1, x_2, \dots, x_n)$ via Bayes rule, and in the simpler case of naïve Bayes, the probability calculation will be performed via the assumption that the individual features are independent.

Nearest neighbor approaches are nonlinear methods for assigning classes. However, rather than calculating a global classifier that partitions the space, nearest neighbor methods utilize a voting method. This method is exemplified by the k-nearest neighbor (KNN) algorithm [27]. In a KNN classifier, the KNN is taken and a simple voting process takes place to determine whether the unknown point belongs to a certain class. For instance,

in a 3-NN classifier, if two of the nearest points indicate that the class of the unknown point is C_i , and a third class is indicated as C_k , the assigned class will be C_j .

The primary benefit of KNN classifiers is the general simplicity of the algorithm as well as its ability to approximate arbitrary nonlinear partition functions between the different classes. However, it suffers from the disadvantage that the classification process is computationally expensive in comparison to the other methods. The classification of a single point requires calculation of the distance between that point and all of the points in the training set, as well as determining the k-smallest distances. This is in contrast to the other methods, that after a relatively expensive training process, the classification process can usually be implemented as a computationally efficient lookup table.

BROAD CHALLENGES

While we have presented a survey on the general basis of most algorithms that currently exist, data mining is still an active area of research. There are three primary unaddressed issues that drive current research.

1. *Scalability and the Curse of Dimensionality.* With the advances in technology, the ability to gather a wide range of information has increased, and thus the feature space that describes a single data point increases as well. However, with a linear increase in the number of features that describe the data, there is a corresponding exponential in the algorithmic complexity. Thus, while Moore's law suggests the same exponential doubling of computational power roughly every 12–18 months, hardware power is not the only answer. It is imperative that as databases get larger, there be a commensurate improvement in the algorithms that conduct classification, clustering, and feature selection.
2. *Noise and Infrequent Events.* Noise and uncertainty in the data are given features. Therefore, the question is how to

design algorithms that functions well in an environment with a significant amount of noise, or at least develop robust methods that quantify the effect of noise upon the results of these algorithms. Furthermore, while it is customary to look for repeated, that is frequent, events to derive rules underpinning a systemic response, it is often the case that infrequent events are the ones of particular interest. Robustly discriminating between an underlying rare event and outliers therefore becomes a critical issue.

3. *Interpretation and Visualization.* The ultimate goal of any data mining, and thus classification as well, is the understanding of the data and developing actionable strategies based on the conclusions. We therefore need to improve not only the interpretation of the derived models but also the knowledge delivery methods based on the derived models. Optimization and mathematical programming needs to provide not just the optimal solution, but also some way of interpreting the implications of the results.

DATA MINING IN CONSTRUCTION BIDDING POLICY

TREFOR WILLIAMS
Professor of Civil Engineering,
Center for Advanced
Infrastructure and
Transportation, Rutgers
University, Piscataway, New
Jersey

Many construction projects are selected using competitive bidding. This is a reverse auction where the lowest bidder wins the project. It is often suspected that winners of construction projects are subject to a “bidder’s curse” because the lowest bid may include an error or omission.

It is useful to examine the nature of construction bids and to study the relationship of the original low bid with the completed project cost. It is possible to hypothesize that construction bids occur in repeatable patterns and that relationships exist among the submitted bids that can allow a prediction of completed project costs.

It is generally accepted that the ultimate cost of a complex project is difficult to predict and subject to variations caused by many different factors [1]. Skamris and Flyvberg [2] have reported that for large construction projects in Denmark, the construction costs are often underestimated. They believe that overoptimism in the initial planning stages of a construction project leads to decisions that misallocate funds. Models that can provide predictions of the magnitude of the project cost would allow owner organizations to plan and budget better for the actual costs of construction projects.

Prices often escalate above the low bid price particularly on new, complex projects. The bid price developed by a contractor for a construction project will include the total of the net estimate with appropriate additions for overhead, profit, and risk margin [3]. Subjective judgment is often used when calculating a bid price. Many other factors affect the

price of the project during construction. These factors include the quality and constructability of the design, management techniques employed by the contractor, location of the project, and macroeconomic conditions.

Change orders are the primary way in which costs escalate during construction projects. Change orders are negotiated contracts that modify the original project requirements. Although the low bidder on a construction project is initially responsible for constructing the project for the original low bid price, changes in the form of change orders inevitably increase the cost of complex and innovative projects. Typical reasons for a change order are differing site conditions, errors or omissions in the project plans, and design changes initiated by the owner.

The primary research problem is to determine if the bidding patterns reflect the uncertainties about a project’s completed cost in repeatable ways. The purpose of this analysis is to study if the individual bids for a project combine into useful patterns that indicate a project’s likelihood to have significant problems, and change orders that would cause extensive cost overruns from the original bid amount. An owner organization could use knowledge of a project’s likelihood for cost overruns at the time of the bid opening to determine if the project should proceed or be reexamined to identify problems. This article will explore how rules can be generated using association and classification from a database of project bidding data.

BIDDING PATTERNS

Various scenarios can be postulated for patterns in submitted bids. A project that is well designed and easily understood by contractors could be expected to have all the bids clustered together, and that project would be constructed with little increase in cost from the original low bid amount. Various strategies and patterns have been identified in the construction literature. In

the early 1990s, a study was undertaken to evaluate construction cost overruns and identify the factors that significantly impact construction cost overruns based on data from over 400 construction projects administered by the Washington State Department of Transportation during the fiscal years 1985 and 1989 [4]. Many factors that had the strongest association with construction cost overruns were identified. It was found that cost overruns increased with the size of the project as well as the number of bidders and with the increased dispersion of the various bids submitted per project. In other words, increased cost overruns appeared to occur on larger projects, projects with greater risks, projects with more complexity, and projects with larger numbers of bidders.

Bidders often bid in systematic ways that may be discernible as bid patterns. For example, a bidder seeing a poor design may bid a low amount, expecting to make money from the change orders that will be issued [5]. Crowley and Hancher [6] have identified three types of bidders. Bidders can be classified as phantom, mistaken, and fair based upon their bidding strategies. Phantom bidders consistently submit bids that are lower than the other bids received on a project. Mistaken bidders submit unusually low bids due to an error or omission. Fair bidders consistently target the market value with their bids. The variability between the bids of fair bidders is caused by minor differences in judgment or assumptions. Of course, the low bidder is contractually obligated to complete the project at the low bid price, but change orders are often issued during construction and increase the project cost.

PURPOSE AND BENEFITS OF ANALYZING BIDDING COSTS AND POLICIES

In this article, the focus is on using data mining techniques to identify patterns in highway projects bidding data that may provide a prediction of the magnitude of a project's cost overrun during construction. Possibly, a project's potential for cost overruns is related to the pattern of the submitted bids. It can be assumed that

bidders for a large construction project have carefully examined the plans and specifications before submitting their bids. Possibly bidders behave in repeatable patterns depending on the characteristics of the project they are bidding for. This knowledge could be exploited by owners leasing projects to determine if the bids received are suitable and as a way of planning for contingency funds to cover a project's construction costs.

BACKGROUND

Various models have been proposed for predicting completed project cost. In particular, multiple regression and neural networks have been applied to develop predictive models of construction costs. Wilmot and Cheng [7] have described the development of a model to estimate overall future highway construction costs in Louisiana. In the model, future construction costs are described in terms of predicted index values based on forecasts of the price of labor, materials, and equipment. Additional factors included in the model are the expected contract characteristics and contract environment. The model produces an index that projects future aggregate costs for groups of projects. The model does not predict the future costs of individual projects.

Emsley *et al.* [8] have developed a neural network model to predict total construction costs in the form of cost per square meter and log of cost per square meter based on input data from nearly 300 building projects. They developed several neural network models that included inputs about the project such as the duration, building function, required mechanical installations, and the requirements for piling. They concluded that the neural network models compared favorably with regression models.

Trost and Oberlander [9] used factor analysis and multivariate regression to develop an estimate score procedure that allows project managers to score an estimate, and then predict its accuracy based on the estimate score. The statistical analysis identified five significant factors: basic process design, team experience and cost information, time allowed to prepare the

estimate, site requirements, and the bidding and labor climate. They produced a regression equation to predict the required bid contingency using these five factors.

DATA MINING: ASSOCIATION AND CLASSIFICATION

Data mining is the process of automatically discovering useful information in large data repositories. Two common techniques for data mining are association and classification. The output of an association analysis is a set of association rules that show those items in the database that form frequently occurring sets [10], whereas a classification algorithm is applied to the bidding data to generate rules that can predict a project's anticipated level of cost overrun above the original low bid amount. Both algorithms automatically identify rules from databases. Association algorithms identify the best-performing rules in the database. Some of the cases in the database may not be included in the generated rule set. Classification algorithms generate a set of rules that will classify all of the items in the database. In this article, data was used to generate example classification and association analyses from highway projects conducted by the Texas Department of Transportation from 1995 to 2000. The database included data from 2765 competitively bid highway projects. For each of these projects, the lowest responsible bidder was selected to perform the work. This analysis considers only the bids of the responsible bidders; rejected bids are not considered.

Software Used for Analysis

The Weka software was used to classify the bidding data and to generate association rules [11]. The Weka software is a collection of machine learning algorithms and data preprocessing tools that have been developed at the University of Waikato in New Zealand. The system is written in Java and will run on most computer platforms. The Weka system is an open-source software and can be obtained from the Weka software web page at <http://www.cs.waikato.ac.nz/~ml/weka/>.

Classification Algorithms Employed

Classification can be defined as the task of assigning objects to one of several predefined categories [10]. Here, the object is a description of the bids submitted for a project and the predefined categories are the level of the completed project cost overrun. Several different classification algorithms were provided in the Weka system. The best-performing algorithm for predicting large project cost overruns was found to be the Ridor algorithm. The Ridor classification algorithm was applied to the Texas highway project bidding ratio data. The Ridor (Ripple Down Rules) algorithm is a machine learning technique that automatically generates rules from a data set [12]. The Ridor algorithm was initially developed to maintain rules for one of the first medical expert systems, and is now routinely used in chemical pathology laboratories to provide interpretive comments to assist doctors in using medical laboratory reports [13]. The Ridor algorithm learns rules with exceptions by generating a default rule. The default or top-level rule is the class of the output that occurs most frequently. Then the algorithm uses incremental reduced-error pruning to find exceptions with the smallest error rate, finding the best exceptions for each exception and iterating [11]. Thus it performs a treelike expansion of exceptions; the exceptions are a set of rules that predict cases other than the default.

Association Algorithms Employed

Several different association algorithms are provided in the Weka system. Through experimentation, two algorithms were found to find interesting relationships in the bidding ratio databases. The best-performing algorithms for predicting the level of the cost increase observed during construction was found to be the Predictive Apriori algorithm and the Tertius algorithm. Using the Texas data, rules were generated using both of these algorithms.

When discussing the generation of association rules two terms, *support* and *confidence*, are important to understand. The support is the number of instances in a database that a rule predicts correctly. The confidence is

the proportion of examples covered by the premise that are also covered by the consequence of a rule. In constructing a method to find association rules it is desirable to find rules that are not too broad (rules that would have broad support yet low confidence) and rules that are too narrow (rules that have high confidence yet apply to only a few cases). The Predictive Apriori algorithm combines confidence and support into a single measure called *predictive accuracy* to generate association rules that provide "...a trade-off between confidence and support which maximize the chance of correct predictions on unseen data" [14]. The Predictive Apriori algorithm implemented in Weka generates the n best association rules, with n selected by the user.

Tertius is an algorithm developed by Flach and Lachiche [15]. The Tertius algorithm uses a heuristic measure, confirmation, to induce rules that are interesting and unusual. Tertius employs a best-first search algorithm that uses an optimistic estimate of the best confirmation of possible refinements of a rule to prune the search.

BIDDING RATIOS

The inputs to the models were ratios that would be available at the time of the bid opening that could potentially describe a pattern in the submitted bids. Williams [16] calculated five ratios that describe the nature of the submitted bids. These ratios are a way of representing the relationships between bids for a project; they are dimensionless and are not dependent on the project magnitude. The rationale for the use of the bid ratios is that ratios describing the "signature" of the bids for a project can give clues about the project's likelihood to experience cost increases during construction. Potentially, bids that are closely bunched together or contain extreme outliers may give clues about the completed project cost. The ratios include the second lowest bid ratio, the mean bid ratio, the maximum bid ratio, and the coefficient of variation of the submitted bids. The formulas used for the calculation of the ratios are given below. A ratio was calculated to compare the second

lowest bid with the low bid amount. This ratio determines if the low bidder and next lowest bidder basically agree about the project cost. The ratio is given in Equation (1).

$$\begin{aligned} &\text{Second Lowest Bid Ratio} \\ &= \frac{\text{Second Lowest Bid} - \text{Low Bid}}{\text{Low Bid}}. \end{aligned} \quad (1)$$

Another ratio measures the difference between the low bid and the mean bid and is given by Equation (2). The purpose is to measure how far the low bid is from the "consensus" bid.

$$\text{Mean Bid Ratio} = \frac{\text{Mean Bid} - \text{Low Bid}}{\text{Low Bid}}. \quad (2)$$

The mean bid ratio may indicate the degree of clustering of the bids. If the ratio of the low bid to the mean bid is large, it probably indicates that the low bidder has submitted an artificially low bid or a project where there is little agreement about costs. Equation (3) shows a median bid ratio that was also calculated as an alternative measure of the low bids deviation from the group consensus.

$$\text{Median Bid Ratio} = \frac{\text{Median Bid} - \text{Low Bid}}{\text{Low Bid}}. \quad (3)$$

A ratio is also calculated relating the maximum bid to the low bid. This ratio indicates the spread of the submitted bids, and indicates if there is significant variation in the range of values of the submitted bids. It is also an indication of the existence of an extremely high bid. The maximum bid ratio is shown in Equation (4).

$$\begin{aligned} &\text{Maximum Bid Ratio} \\ &= \frac{\text{Maximum Bid} - \text{Low Bid}}{\text{Low Bid}}. \end{aligned} \quad (4)$$

As a way of measuring the agreement between bidders, the coefficient of variation

was calculated. The coefficient of variation is given by Equation (5).

$$\text{Coefficient of Variation} = \sigma/\bar{x}. \quad (5)$$

Where σ = the standard deviation of the bids submitted for a project, and $\bar{x}$ is the mean of the submitted bids. The coefficient of variation is a measure of the spread of the submitted bids and is a measure of the agreement between the bidders.

STATISTICAL RELATIONSHIP BETWEEN RATIO LEVELS AND COST OVERRUNS

Williams *et al.* [17] have found that there is a statistically significant link between the level of the ratios and the completed project cost. Their study was conducted using this highway-bidding data from Texas. There was found to be statistically significant difference in the value of the bidding ratios between projects completed at a cost near the low bid amount and projects where the completed project cost differed significantly from the low bid amount. Higher values of the ratios are observed for projects completed with significant deviations from the mean. Projects completed near the original low bid amount tend to have lower values of the ratios. It was also noted that the elevated ratio values seem to occur for projects that have large cost increases and for projects that are completed for significantly less than the original bid amount. It was also found that due to the noise in the bidding data, it was difficult to construct regression or neural network models that could exploit knowledge of the bidding ratios to predict the magnitude of a project's likely cost increase during construction. Therefore, data mining techniques that are able to generate association and classification rules from the data are a useful area to explore, so as to determine if they can provide useful predictions.

PREPARING THE BIDDING DATA FOR CLASSIFICATION AND ASSOCIATION

The focus of the analysis is to attempt to identify in advance, projects that will have

a large cost increase. A large percentage of the projects are completed for near or less than the low bid amount (1712 projects out of the total number of 2765 projects in the database). Each record in the database consisted of the data for one project. Each project had a value defined for the five ratios described above, and for the magnitude of the low bid amount. These could take on the nominal values of "low", "medium", or "high." The ranges for each variable were determined by the values that placed one-third of the projects at each level. Each project also had its cost overrun recorded as "Near", "Overrun", or "BigOverrun." A "Near" project was completed for less than or up to a cost overrun of 5%. An "Overrun" project was completed for a cost overrun of between 5% and 10%. A "BigOverrun" project was one in which the completed project cost exceeded the low bid amount by more than 10%. There were 444 projects in the Overrun category and 609 projects in the BigOverrun category.

Table 1 shows the relationships in the Texas highway between the level of three of the bidding ratios and the weighted average percentage difference between the original low bid amount and the completed project cost. The projects in each grouping were weighted according to their low bid magnitude. In Table 1, it can be observed that elevated levels of the ratio values are associated with projects that tend to have a larger percentage difference between the completed project cost and the low bid. For example, projects where all of the ratio values are low tend to have a lower cost overrun than projects where all of the ratio levels are high. However, it can also be seen that there are many complex relationships between the levels of the three ratios and the project's ultimate cost increase. In addition, examination of individual projects in the database indicates that there are many exceptions to general trends. There are some projects in the database that have large cost increases but low ratio values. These many exceptions make it difficult to produce accurate classification rules and association rules. The variability in the data will be reflected in the results shown in Table 1.

Table 1. Weighted Average Percentage Difference between Completed Project Cost and Low Bid for all Texas Projects

Coefficient Index Value	Second Lowest Bid Index Value	Maximum Bid Index Value	Number of Projects	Weighted Average Percentage Difference
High	Low	Medium	53	13.94
Medium	Medium	Low	31	9.08
High	High	High	421	7.94
Medium	Low	Low	49	7.28
High	High	Medium	51	6.87
Low	Low	High	28	6.85
Medium	Medium	High	54	6.61
High	Medium	High	187	6.52
High	Medium	Medium	35	6.45
Medium	High	Medium	224	6.20
Low	Low	Low	380	5.96
Low	High	Low	55	5.85
Low	Low	Medium	32	5.74
Medium	High	Low	41	5.59
Medium	High	High	56	5.15
High	Low	High	173	4.88
Medium	Medium	Medium	231	4.62
Low	Medium	Medium	55	4.34
Low	Medium	Low	328	4.27
Low	High	Medium	33	3.58

GENERATING CLASSIFICATION RULES

Model Inputs and Generated Rules

A rule set was constructed using the Ridor algorithm. Using the Weka software, the bidding ratio data were first preprocessed to identify the best ratios to be used to generate classification rules. Using the Weka data preprocessor, an attribute selection algorithm was used that considered the predictive value of each attribute individually, along with the degree of redundancy among them. The attribute selection method employed a greedy hill-climbing search method with backtracking to select the best attributes [11]. Using the attribute selection method employed in Weka indicated that the second lowest bid ratio, the mean ratio, the coefficient of variation, and the magnitude of the low bid were the best predictive indications. Therefore, the maximum bid ratio and the median bid ratio were not considered in the generation of rules.

Figure 1 shows the rules that were generated. Six rules were generated in total. The antecedents for each rule, the left hand

side of the rule, are nominal values of the level of the coefficient of variation, the low bid ratio, and/or the second lowest bid ratio. These variables can take the value of low, medium or high. The right hand side of the rule is the prediction, giving the level of the project cost increase as “Near”, “Overrun”, or “Big Overrun.”

The major class of the output attribute is a prediction of the project overrun to be near the original bid amount. By default, this becomes the top-level rule. An examination of the rules shows that the exception rules generated are instances where the antecedents in the rules, the ratio levels, are of a high or medium level and the project’s final cost is predicted to be a “BigOverrun” or an “Overrun.” This result confirms that elevated levels of the ratios are generally associated with increased cost overruns. For the exception rules in Fig. 1, the numbers in parentheses indicate the total number of training cases covered by the rule and the second number is total number of cases that would be classified incorrectly by the rule.

The first exception rule indicates that all projects with a median bid ratio level of

Figure 1. Classification rules generated using the Ridor algorithm.

medium will have a large overrun. However, examination of the output indicates that the rule is incorrect for about 58% of the test cases. A better rule is the final exception rule generated where if three ratios are simultaneously high, then a large cost overrun is predicted. This rule is correct for 11 out of 20 test cases.

Performance of the Classification Rules

To test the performance of the rules, a test set was used which included 33% of the data selected at random. The other 67% of the data were used to generate the rules. The

Table 2. Confusion Matrix for Classification Rule Predictions

Actual Cost Overrun	Predicted Cost Overrun			
	Near	Overrun	Big Overrun	Total
Near	307	21	267	595
Overrun	81	6	69	156
Big Overrun	87	3	100	190
Total	475	30	436	941

numbers in brackets in Fig. 1 at the end of the exception rules indicate the cases in the test set covered by the rule and the second number is the number of cases incorrectly classified by the rule. The success of the generated rules in providing predictions is given by the confusion matrix in Table 2. In the confusion matrix, there is a row and column for each predicted level of the project cost overrun.

The confusion matrix indicates that the generated rules produced correct predictions for 43.89% of the projects. However, the model classified 100 out of 190 projects (53%) with large cost overruns correctly. Projects that were completed “Near” the original low bid amount were predicted correctly 65% of the time. It was found to be difficult to classify the “Overrun” category because it has a smaller number of cases than the “Near” or “BigOverrun” categories.

ASSOCIATION RULES GENERATED

Rules were generated using both the Tertius and Predictive Apriori association algorithms. Using the Weka software, the bidding ratio data were first preprocessed to identify the best ratios to use so as to generate classification rules. Using the Weka program, an attribute selection algorithm was used that considered the predictive value of each attribute individually, along with the degree of redundancy among them. The attribute selection method employed a greedy, hill-climbing search method with backtracking to select the best attributes [11]. Using the attribute selection method employed in Weka indicated that the second lowest bid ratio, the mean ratio, the coefficient of variation, and

Figure 2. Predictive Apriori best association rules for different levels of cost overrun.

the magnitude of the low bid were the best predictive indications. Therefore, the maximum bid ratio and the median bid ratio were not considered in the generation of rules.

Predictive Apriori Rules

Figure 2 shows some of the best rules from the computer output from the Predictive Apriori algorithm run. The one hundred best rules were generated. The best rules for the prediction of each of the three levels of cost overrun are shown in the figure. The underlined italic number is the ranking of the rule as generated by the computer software. The rule premise (the left-hand portion of the rule) is made up of the level of

various combinations of the bidding ratios. The number after the premise of each rule is the number of cases in the database that displayed these combinations of the bidding ratios. Each ratio could have the value of low, medium or high. The consequence of the rule is the level of cost overrun. This is the portion of the rule to the right of the arrow. The number after the outcome of the rule is the number of cases in the database that are correctly classified. The predictive accuracy is shown at the end of each rule. This number is a combination of two metrics: the confidence in the rule, and the support for the rule. The confidence in a rule is the proportion of examples covered by the premise

Figure 3. Best rules generated by Tertius algorithm.

that are also covered by the consequence of the rule. The coverage is the number of instances that are correctly predicted. Highly accurate predictions have a predictive accuracy approaching one. The output using the Predictive Apriori algorithm shows that it is possible to develop highly accurate rules to predict when the project cost overrun will be near to the original low bid amount. However, it was more difficult to produce accurate rules that can predict both, overruns and large cost overruns. Four out of the five best rules for predicting a BigOverrun had a high level of the coefficient of variation ratio.

Rules Generated by the Tertius Algorithm

Figure 3 shows the top 15 ranked rules generated by the Tertius algorithm. This algorithm appears to be more successful in identifying rules related to large project cost overruns. In the output shown in the figure, the two numbers provided for each rule are the value of the degree of confirmation calculated for

the rule, and the relative frequency of counterinstances. The rules are ranked in order of the value of the confirmation heuristic. When this second number, the relative frequency of counterinstances, is zero it would indicate that all of the cases predicted by the body of the rule were correct. Examination of the output indicates that rules containing low levels of the ratio values were generated that predicted a completed project cost near the original low bid amount. Several rules were generated that predicted large cost overruns when ratio levels were high; however, these rules had a much higher frequency of counterinstances.

CONCLUSIONS

This exploration of the use of the Ridor classification algorithm showed some potential for producing rules that can predict construction project cost overruns. In particular, the rules are able to predict projects with a greater than 10% cost overrun with a success rate of

53%. However, examination of the bidding data indicates that the existence of some contradictory cases in the test set make it difficult for the Ridor algorithm to produce rules that are highly accurate.

The use of association algorithms also showed some potential for producing rules that can indicate the level of cost increase a construction project is likely to have. The analysis has shown that elevated levels of the bidding ratios are more likely to be associated with projects that have high cost overruns. Both methods of producing association rules were able to automatically produce rules that indicated projects completed near the low bid amount with a high level of accuracy. A disadvantage of the association rules was their inability to predict an outcome for all possible combinations of input variables.

The research indicates that analysis of the submitted bids and the patterns they may contain are a fertile area for further research. An enhanced understanding of the bidding strategies used by construction contractors can allow owners to better understand when projects may be prone to cost overruns during construction. Possibilities for future research include the exploration of ways to "cleanse" the data-set to remove anomalous cases or cases that are outliers, consideration of other classification methods and algorithms, and methods of combining rule-based prediction with subjective expert input.

COUNTERTERRORISM ANALYSIS USING DECISION TREES AND PROBABILITY ASSESSMENT

From its early inception, the Department of Homeland Security (DHS) has been concerned about attacks on commercial airlines using surface-to-air missiles, called *Man Portable Air Defense System* (MANPADS). Such missiles can be guided by an automated infrared detection system that targets the heat of the airplane's exhausts or by laser target identification from a person on the ground. In 2004, DHS awarded research and development funding for protective measures against MANPADS attacks. The researchers sought to modify protective measures currently used on military aircraft. von Winterfeldt and O'Sullivan [1] perform a decision analysis to determine whether such directed infrared countermeasures (DIRCMs) are cost effective.

Figure 1 illustrates a decision tree for the MANPADS decision. The sequence of events that can lead to a downed airliner is a MANPADS attack, a failed interdiction, a hit on the plane, and a fatal crash. If no countermeasures are installed then the probabilities of each event conditioned on the occurrence of the previous events are denoted as p , $(1 - q)$, h , and r . If countermeasures are installed, then the probabilities are modified by parameters representing the effectiveness of the countermeasures. Thus, the probabilities of each event conditioned on the occurrence of previous events and countermeasures are denoted as $(1 - d)*p$, $(1 - f)*(1 - q)$, $(1 - e)*h$, and $(1 - g)*r$. This implies that $(1 - d)$ is the proportional reduction in the probability of a MANPADS-based attempt, $(1 - f)$ is the reduction in the

probability that interdiction fails, $(1 - e)$ is the reduction in probability that the missile hits the plane, and $(1 - g)$ is the reduction in probability that the plane crashes if countermeasures are installed. The costs are also parameterized. Table 1 shows a range and base estimate for each probability parameter and the costs associated with each outcome.

At base parameter values, the optimal decision is to install countermeasures with an expected cost of \$15 billion in comparison to \$19 billion for no countermeasures. This parameterized decision tree is effective in capturing the structure of the decision problem with a simple model, and allows the significant uncertainty about the parameters of the problem to be tested. The question then turns to the parameters that are driving the optimal decision. von Winterfeldt and O'Sullivan [1] describe the creation of a spreadsheet decision-support tool that allows decision makers to change the parameters within the ranges in Table 1 and to test the resulting optimal decision. Varying parameters at the decision makers' discretion can be useful to allow them to see the potential changes in the optimal decision, but it can also be useful to perform sensitivity on all the parameters to see how and when they change over specified ranges. We will not reproduce the tornado diagram here for brevity, but we can describe key findings. The largest effect on expected cost comes from the swing from the minimum to maximum value of EL (economic loss/fatal crash). With increase in EL from the base value, the decision remains to install countermeasures, but as EL decreases the optimal decision switches to no countermeasures. The switch is calculated to occur at \$74.3 billion. The same pattern repeats for the next five most influential parameters: the cost of countermeasures, the probability of an attack attempt in the next 10 years with no countermeasures, the probability of a crash given a missile hits with no countermeasures, the percent loss in passenger volume given a missile hit and a safe landing, and the cost of a false alarm.

Bakir [2] repeated the parameterized decision tree approach for decisions about containers entering the US by truck over

Table 1. Decision Tree Inputs—Probabilities and Effectiveness Ranges [1]

Parameter	Min	Base	Max
<i>Probabilities</i>			
p—attack attempted in 10 years	0	0.5	1
q—interdiction/attempt	0	0	0.25
h—hit/attack	0.5	0.8	1
r—crash/hit	0	0.25	0.5
<i>Countermeasure effects</i>			
d—deterrence effect	0	0.5	1
f—interdiction effect	0	0	0.25
e—diversion/destruction effect	0.5	0.8	1
g—crash reduction effect	0	0	1
<i>Consequences</i>			
LL—fatalities/crash	0	200	400
CP—cost of plane (millions)	0	200	500
EL—economic loss/fatal crash (billions)	0	100	500
a—percent loss/hit and safe landing (%)	0	25	50
b—percent loss/miss (%)	0	10	25
FA—number of false alarms/year	0	10	20
CC—cost of countermeasures (billions)	5	10	50

the Mexican border. Three decisions are considered, improving transportation security, installing screening equipment on the Mexican side of the border, and whether to screen on the US side of the border with advanced

scintillator portals (ASPs) or keep existing radiation portal monitors (RPMs). The chain of events that lead to a successful attack is first an attempt to smuggle a nuclear threat, failure to detect the threat prior to reaching

**Figure 1.** Decision tree for MANPADS (adapted from [1]).

Figure 2. A decision tree for the container-screening problem with one screening.

the border, failure to detect on the Mexican side of the border, failure to detect on the US side, the terrorist deciding not to detonate at the border, failure to interdict within the US, and lastly the success of detonation at the intended target. Within Bakir's analysis is the assumption that if an alarm sounds when screening the container, then the container is sent for secondary screening and inspection. Bakir [2] provides a wealth of probability and cost estimates and performs a comprehensive sensitivity analysis on each parameter. For instance, we would have to screen 10 billion containers to detect four true threats. However, we would also detect 249,999,996 naturally occurring radioactive material (NORM) sources (regular goods that give off radiation, such as ceramic tile and irradiated iron). Inspecting containers

because of NORM sources is costly and delays the cargo. Bakir [2] concludes that US Customs and Border Protection (CBP) should not implement new ASP technology.

Merrick and McLay [3] extend Bakir's analysis, examining specifically whether screening should be performed at all. Figure 2 shows a decision tree for this decision that includes whether to inspect the container if an alarm sounds. Given Bakir's base parameter values, the answer is no. The value of information from screening is not sufficient to justify the cost of screening and the cost of false alarms from NORM sources. However, such an analysis ignores the deterrence effect of screening. Bakir parameterizes this effect and assumes that the probability of an attempt reduces by an estimated factor if additional security is

added. Merrick and McLay [3] find that the probability of an attempt if containers are not screened must be at least 1.6 times the probability of an attempt if they are screened to make screening economically worthwhile. The question is how to determine the effect of screening on terrorist decisions. This is more the prevue of game theory, but methods such as those in Parnell *et al.* [4] are potential solutions and are discussed in the section titled “Counterterrorism and the Intelligent Adversary.”

COUNTERTERRORISM ANALYSIS USING VALUES AND OBJECTIVES

Keeney [5] proposes that decision makers consider values and objectives in the analysis of counterterrorism decisions. Keeney developed 14 attributes for evaluating the outcomes of such decisions from the defender’s perspective. Six attributes are costs, namely

- direct and indirect costs to individuals
- direct and indirect costs to businesses
- direct and indirect costs to the government.

Three other attributes are counts of the effect of the attack on individuals, namely:

- the number of deaths caused by the attack;
- the number of victims disabled by the attack;
- the number of jobs lost because of the attack.

These measure the effect of the attack on the victims, both directly and indirectly. The five other attributes are associated with the effects on continuing terrorist operations and US society, including

- the effect on recruitment of future terrorists;
- the number of dollars flowing to support terrorism;
- the level of political support for US actions to counterterrorism;

- the number of US citizens experiencing limits to their freedom;
- the number of citizens experiencing fear and despair.

Keeney [5] also illustrates a value model of terrorist preferences developed with subject matter experts at Lawrence Livermore Laboratory. Keeney lists three terrorist objectives for a decision related to terrorist attempts to enrich plutonium for a radioactive dispersal device.

1. Maximize the amount of plutonium acquired.
2. Maximize the purity of the plutonium.
3. Minimize the radiation danger to the terrorist.

The experts determine the following attributes:

- X_1 plutonium extracted, measured from 10 to 2500 grams (gPu)
- X_2 purity of stolen material, measured from 0 to 333 grams of uranium per liter of material (gU/L)
- X_3 radiation dose, measured from 0 to 100 Rads/h.

Keeney [5] creates the utility function $u(x_1, x_2, x_3)$, where x_i is a specific level of attribute $X_i, i = 1, 2, 3$. For example, $u(150, 27, 5)$, which denotes the utility of the terrorist obtaining 150 g of plutonium with purity 27 gU/L that gives off 5 Rads/h. Keeney establishes the appropriateness of the additive or multiplicative utility function by determining if independence assumptions are upheld [6]. Holding two attributes at a constant level and varying the third, one can elicit single attribute utility function curves. Keeney elicits example utility function using the lottery indifference technique. Weights for either the additive or the multiplicative utility function are then elicited using other indifference judgments.

Leung *et al.* [7] consider bridges as vulnerable targets for terrorist attacks and rank the most likely targets. Leung *et al.* uses a risk filtering, ranking, and management (RFRM) method for their counterterrorism

analysis which builds on hierarchical holographic modeling (HHM) to identify risks. The risks are then ordered to help the decision maker prioritize. Risk management is then used to determine potential plans of action to protect the bridges most at risk. Other applications of such multiple objective methods include ranking various types of critical infrastructures to protect [8,9]. Buckshaw *et al.* [10] implement a similar structure when evaluating alternatives designed for the protection of critical information systems. Feng and Keller [11] used a multiple objective decision analysis approach to assess potential distribution plans in a specified region of potassium iodide to counter the release of radioactive iodine due to a terrorist attack or an accident.

Keeney and von Winterfeldt [12] analyze statements made by Al Qaeda to determine the objectives implied. They determine five strategic objectives.

1. Inspire and incite Islamic movements and the Muslim masses of the world to attack the enemies of Islam
2. Expel western powers from the Middle East
3. Destroy Israel
4. Establish Islamic religious authority in the Middle East
5. Extend Islamic authority and religion into new areas of the world.

Keeney and von Winterfeldt then define two groups of fundamental objective; one group related to growth of the movement, and one related to military outcomes. The growth related objectives are

- G1. Main status as the primary Middle Eastern force to be reckoned with,
- G2. Created homegrown terror cells in the US and Western Europe,
- G3. Win the hearts and minds of the Muslim population,
- G4. Maximize financial contributions from supporters,
- G5. Recruit new followers.

The military objectives are

- M1. Attack US targets,
- M2. Cause economic loss for the US,
- M3. Expel the Americans from Iraq,
- M4. Kill large numbers of infidels.

An understanding of Al Qaeda's objectives can enrich existing decision analyses. For instance, Merrick and McLay [3] consider a two-objective value function for the container-screening decision that includes elements of objectives G3, G4, and G5 in the growth area, and M1, M2, and M4 in the military area. They find that depending on the value function used, the optimal container-screening decision can change significantly from that obtained with a single cost objective.

COUNTERTERRORISM AND THE INTELLIGENT ADVERSARY

Game theory has also been widely applied in counterterrorism to model the decisions of the terrorist adversary, including general strategy and defense modeling [13–17], and specific applications, such as protecting power transmission systems [18] and commercial airlines [19]. In this section, we will concentrate on adversarial methods that use decision analysis as their primary technique.

Paté-Cornell and Guikema [20] created a model for setting priorities among threats and countermeasures that combines aspects of probabilistic risk analysis, decision analysis, and game theory. Figure 3 shows the influence diagrams used. The influence diagram in Fig. 3a is the terrorist decision, and can be repeated for multiple potential terrorist groups. The authors solve the terrorist influence diagram to discover the utility of each potential terrorist alternative. These utilities are then transformed into probabilities of terrorist behavior for use in the US influence diagram in Fig. 3b. As one of the earliest combinations of decision analysis and game theory in the post 9/11 emphasis on counterterrorism, the approach includes a sequential consideration of the terrorist decision and then the counterterrorist. However, the authors also point out that such thinking

Figure 3. Influence diagrams for both terrorist and US [20].

Figure 4. Decisions trees including decisions for both terrorist and US [4].

can be iterated between the two adversarial decisions.

Parnell *et al.* [4] consider the problem of defending against bioterrorism. They consider two decisions for the counterterrorist, specifically whether to add a city to the biowatch program, and whether to store and deploy vaccines for use after a bioterrorism attack. The terrorist decision is what kind of biological agent to use in an attack. These decisions are sequential and can, thus, be represented in a single decision tree or influence diagram. The decision tree is shown in Fig. 4.

To simplify solution of the decision tree, Parnell *et al.* assume that the terrorist objectives are diametrically opposed to the defender's. That is, if we aim to minimize the expected total cost of defense and attacks, then they aim to maximize the same measure. Solving Fig. 4 then follows the standard backward induction method for solving decisions trees, where one starts at the right (end) of the tree, takes an expected value at any probability node, takes the "best" expected value at any decision node, and folds the tree backwards. However, at a terrorist decision node "best"

is interpreted as the maximum, and at a US decision node “best” is interpreted as the minimum. It should be noted that this also assumes that the terrorists share our same degree of belief, or probabilities, about the likelihood of random outcomes in the decision tree. Paté-Cornell and Guikema [20] make no such assumptions about sharing probabilities and opposite objectives, but their solution method is less developed.

Insua *et al.* [21] propose an approach called *adversarial risk analysis* (ARA) to analyze counterterrorism decisions. ARA is a combination of game theory and Bayesian decision analysis. In its simplest form, ARA can mirror Parnell *et al.* [4]. However, there are two additional facets. First, ARA considers the state of knowledge about terrorist beliefs and preferences. For instance, if we believe that the probability that terrorists can obtain a particular biological agent is 0.05, we do not have to assume that they also believe this is the probability. Instead, we can place a prior distribution on their probability, iteratively sample their probability, and solve their decision to obtain a probability distribution over their actions. Second, ARA allows for simultaneous decisions in the parlance of game theory, not just sequential decisions like Fig. 4. The term simultaneous refers to a terrorist decision and a US decision where neither knows what the other has chosen when they make their decision. As simultaneous decisions are the purview of game theory, we shall leave discussion of such methods to that section of the encyclopedia.

DECISION ANALYSIS CONCLUSIONS

Decision analysis can be used in a variety of ways to help the decision maker understand the decision in its full context and to accurately assess alternatives and trade-offs among the fundamental objectives. We have discussed approaches to counterterrorism decisions that use decision trees and influence diagrams with single attributes, multiple objectives and multiattribute utility functions, and sequential game theory formulations including adversarial decisions. These formulations lay the groundwork for

substantial research to come that should prove beneficial not just for counterterrorist decisions.

DECISION MAKING UNDER PRESSURE AND CONSTRAINTS: BOUNDED RATIONALITY

ALEX KIRLIK

SVEN BERTEL

Human Factors Division and Beckman
Institute for Advanced Science and
Technology, University of Illinois at
Urbana-Champaign, Urbana, Illinois

Concepts of rationality have evolved over centuries [1], and models for both augmenting human rationality, such as the many techniques found in this encyclopedia, and for describing and understanding unaided human rationality, continue to be revised [2]. In this light, our understanding of the “bounds” of human rationality is ever changing, and as such, the meaning of the term “bounded rationality” has both a historical lineage and a rapidly growing set of contemporary associations. The aim of this article is to both situate the concept of bounded rationality in a historical perspective and to trace the many ways in which the original concept has been, and continues to be, developed, elaborated, and revised through psychological research.

ORIGINS

The concept of bounded rationality is typically credited to Simon [3] who noted that, under the constraints and time pressure of much of everyday life, people are incapable of making decisions according to the types of normative procedures and models described previously in this section. Simon [4] put the matter bluntly:

“The SEU model assumes the decision maker contemplates, in one comprehensive view, everything that lies before him. He understands the range of alternative choices open to him, not only at the moment but the whole panorama of the future. He understands the consequences of each of the available

choice strategies, at least up to the point of being able to assign a joint probability distribution to future states of the world. He has reconciled or balanced all his conflicting partial values and synthesized them into a single utility function that orders, by his preferences for them, all these future states of the world. When these assumptions are stated explicitly, it becomes obvious that SEU theory has never been applied, and never can be applied—with or without the largest computers—in the real world.”

Simon goes on to explain that purported “applications” of SEU (subjective expected utility) theory always involve either substituting a highly abstracted problem for the actual problem in its full complexity, or else a microproblem that has been neatly carved out of a more complex reality.

Satisficing and Simon’s Scissors

Two concepts are central to Simon’s original conceptualization of bounded rationality, which he considered to be the “behavioral alternative” to normative theory such as SEU. The first is “satisficing.” Whether it is bees searching for nectar, trout searching for insects or people searching for a restaurant, Simon observed that biological creatures do not optimize but instead tend to select the first decision option that exceeds a specified aspiration level. Although some contemporary psychological research conducted in the name of bounded rationality nevertheless holds on to one or another notion of constrained optimization, it is important to note that Simon himself explicitly rejected this view: “bounded rationality is not the study of optimization in relation to task environments” [5].

As will be discussed in the following, those following in Simon’s footsteps have fractured into two general camps on whether or not bounded rationality should be understood in optimizing terms or instead by appeal to some other metaphors or mechanisms. At this point, suffice to say that Simon’s original

formulation of bounded rationality made no appeal to evolutionary, biological or cognitive mechanisms that optimize in the sense of the term used elsewhere throughout this *Encyclopedia*.

A second core concept in Simon's original conceptualization is the metaphor of a pair of scissors to describe the relationship between a decision maker and a decision environment. A deeper understanding of bounded rationality can emerge only by research that explicitly examines both "the structure of task environments and the computational capabilities of the actor" in terms of "a scissors [with] two blades" [6]. Just as the cutting power of a pair of scissors arises in the mesh of the two blades, the decision competence of an actor can be understood only by examining the degree to which an adaptive mesh exists between the actor's decision strategy and the structure of a decision problem.

Simon introduced this metaphor to hammer home the notion that what is rational and what is not is not, *per se*, a property of the decision maker, nor a decision technique. Instead, rationality must be understood to be a relational property of the actor–environment system. In some environments (such as a casino), using a decision strategy of blind guessing may be said to be completely rational in this light. As is the case with the concept of satisficing, Simon's ecologically oriented scissors metaphor for understanding bounded rationality has continued to be influential. However, this influence has played out in different ways in the study of cognition, judgment, and decision making by various psychological schools. While the alternatives will be discussed in the following, here it is sufficient to observe that all those performing research today in the name of bounded rationality make some type of appeal to the notion that the essence of rationality lies in the degree of fit between cognition and the structure of a decision or task environment.

WHY IS BOUNDED RATIONALITY RELEVANT TO OR AND MS?

Before moving on to describe how the original conceptualization of bounded rationality

has played out in contemporary psychological research, it is worthwhile to address the question of why the student of operations research and management science should care about the psychology of judgment and decision making. Aren't the many methods, models, and techniques described elsewhere in this *Encyclopedia* a testament to the bounded (i.e., limited) nature of unaided human cognition, and thus to be considered as replacements for human cognition whenever possible? Or perhaps even more generally, even if a formal technique for decision making is unavailable, should not a decision maker always strive to be as analytical (i.e., as unbounded) in thinking as possible?

Here, we are not referring to the trivial observation that most people believe that some decisions are still best left in the hands of the expert or the wise, or that none of us break out the full resources of decision analysis or related analytical techniques for every mundane problem. (Though some cases should make us pause: Gigerenzer (7, p. 26) relates the case of Harry Markowitz, winner of the 1990 Nobel prize for his research on optimal asset allocation. Despite inventing an optimization technique for maximizing return while minimizing risk, Markowitz himself used the widely used heuristic of allocating $1/N$ of his assets to each of his N investments to manage his own retirement portfolio—Gigerenzer goes on to describe a study in which none of a dozen asset allocation algorithms, including Markowitz's, was able to outperform the $1/N$ heuristic in seven stock allocation problems).

The reasons that we *do* raise this question are two-fold. First, an enormous body of research has been conducted in the guise of bounded rationality demonstrating often stark departures of the outcomes of intuitive human judgment and decision making with the prescriptions of rational models (see ***Paradoxes and Violations of Normative Decision Theory***). Much of this research, which is often taken to paint a rather dismal picture of unaided human cognition, must be considered in light of the fact that it typically does not truly pit intuition versus analysis on a level playing field.

Rather, such research typically compares the judgments and decisions of unaided cognition against the outcome of an analytical procedure that has been flawlessly executed by a human who is an expert at using that procedure. Only rarely, such as in the case of Hammond *et al.* [8], have studies been conducted to *directly* compare a human's use of an intuitive strategy for performing a task with that *same human's* use of an analytical procedure for performing the task. Hammond and his coworkers found that, in their study of professional highway engineers (judging highway capacity, safety, and aesthetics) that performance was best when the mode of cognition induced (e.g., analysis versus intuition) was most consistent with the nature of the various judgment tasks (i.e., in some cases intuition outperformed analysis). Results such as these should make us pause when making any blanket statements about recommending that all decision makers should try to be as analytical as possible, in all task situations.

Second, and due largely to the recent failures of the US financial system, much serious thought is now being given to the wisdom of turning over near-complete responsibility for the real-time evaluation of risk and even trading authority to computer-based models resulting from financial engineering, economics, and related research. Bernstein (9, p. 6) has summed up the matter as follows:

The story that I have to tell is marked all the way through with a persistent tension between those who assert that the best decisions are based on quantification and numbers, determined by patterns of the past, and those who base their decisions on more subjective degrees of belief about the uncertain future. This is a controversy that has never been resolved.

Lacking any resolution, those involved with developing and prescribing the use of analytical techniques such as those presented in this encyclopedia should be mindful of the trade-offs one incurs when determining whether particular judgments or decisions are best made by analytical models, by knowledgeable humans, or perhaps by joint human–technology systems [10].

To take just one example, intuitive judgment often yields estimates that are imprecise, yet often relatively accurate in the sense of being centered around the correct answer, while the errors of analysis tend to be much fewer in number but potentially sizable in magnitude [8]. This observation, originally due to mid-twentieth-century psychologist Egon Brunswik (11, Fig. 22) emerged from Brunswik's pioneering investigations into the relative strengths and weaknesses of highly intuitive processes such as perception and the more analytical processes we typically describe as "thinking." This phenomenon is already familiar to anyone who has graded an exam on which a student using a calculator (an analytical procedure) provided a probability as an answer with a value less than 0 or greater than 1. It is difficult to conceive how any student with an appreciation of the meaning of probability could arrive at such an answer using intuitive, as opposed to analytical, cognition. Trade-offs between intuition and analysis are especially important when prescription involves training or implementing decision-support technology in operational contexts, where decision makers are unlikely to possess the expertise needed to understand the rationale underlying, and any limitations of, analytical decision strategies they may be trained to use, or assumptions and approximations associated with the decision algorithms embodied in computational aids.

CONTEMPORARY RESEARCH ON BOUNDED RATIONALITY

As mentioned previously, Simon's original conceptualization of bounded rationality has been cited as being central to a wide variety of contemporary research programs on judgment and decision making. Indeed, many of these programs are topics of entire articles in this section (see *Paradoxes and Violations of Normative Decision Theory*; *Fast and Frugal Heuristics*; and *The Naturalistic Decision Making Perspective*). Each of these articles provides a definitive statement of each approach and overview of research in

each respective area, so we will not deal with these areas in depth here.

Instead, experience has taught us that students of bounded rationality, whether they be from psychology or OR/MS, seeking an introduction to this behavioral research often experience significant difficulty in coming to understand how each of the many contemporary approaches to bounded rationality relate. To take just one notable example, at a very general level one can see vast differences across these approaches and research programs in the overall evaluation of the competence of human judgment and decision making, ranging from highly pessimistic to largely optimistic. As such, the purpose of the remainder of this article will be to provide a set of distinctions that will hopefully organize this large, and often apparently conflicting, literature.

Multiple Conceptions of Bounded Rationality: Some Distinctions

In the following sections, we make three distinctions to clarify the ways in which bounded rationality research has been extended since Simon's original work.

Judgment versus Decision Making. Although differences of opinion exist over whether it is useful to make a sharp distinction between bounded rationality in judgment as opposed to bounded rationality in decision making [12,13], we have found such a distinction to be of heuristic value. A decision is an irrevocable selection of a course of action from among a set of alternatives. In contrast, a judgment is an estimation (or prediction, inference, diagnosis, etc.) of a past, present, or future state, event, or value of a variable. In this light, a weather forecaster *judges* that a hurricane will make landfall at a specified location, and on this basis, along with a consideration of various costs and benefits, a public official may *decide* to order an evacuation on the basis of this judgment.

This distinction is useful for organizing the literature on bounded rationality because clear cases exist where a research program focuses solely on judgment (with little to say about values or utilities) and another

research program focuses instead on decision making. In the latter case, to focus on how competing alternatives are selected, the (often) significant amount of information about alternatives, consequences, and their likelihoods, and so forth are simply provided to the decision maker, when in reality, this information must be obtained by the decision maker using prior judgment. Clear cases of such research programs involve much of the material in the related articles mentioned above, in which experimental participants are presented with lotteries consisting of multiple options from which the participant is asked to select. In naturalistic decision-making research, in contrast, the tasks being studied nearly always involve studies of humans, often professionals, making various judgments (e.g., situation assessments) followed by the selection of an irrevocable course of action (e.g., decision making).

This being said, no heuristic is perfect, and clear cases exist where research is indeed focused on choices and decisions, but where the cognitive mechanisms involved are either primarily or even solely judgmental in nature. Judgment researchers understand tasks to be comprised of a set of probabilistic cues, or fallible indicators [11], and a criterion to be estimated on the basis of those cues (as opposed to a decision analyst or researcher who understands a task to have the content and format of a decision tree). For example, a typical judgment task would involve estimating the prospective success (the criterion) of a graduate student on the basis of cues such as undergraduate GPA and standardized test scores that are known to have only limited predictive validity.

In most of the literature on humans' abilities to make such judgments, the gold standard for the assessment of judgment performance is the best linear-additive model relating cues to the criterion as determined by linear regression [14,15]. In such judgment models, the β weights associated with each cue are interpreted to indicate the relative weight or importance the judge places on that cue. High levels of judgment performance are associated with cue weightings that mirror the objective or "ecological" validities of the cues in the task ecology,

although Dawes [16] has demonstrated that “improper” (i.e., equally weighted rather than ecologically accurate) linear models are often sufficient to describe human judgment, once the relevant cues are known.

Some of the difficulty involved in maintaining an adequate distinction between judgment and decision making, and thus in understanding how these literatures are related, almost certainly arises due to the fact that in many cases the gold (prescriptive) standard for the assessment of decision, rather than judgment, performance also takes the form of a linear-additive model. Assuming certain conditions, such as mutual utility independence, are met, normative models in multiattribute decision tasks [e.g., MAUT (multi-attribute utility theory)] also take the form of a linear-additive model. But in contrast to the case in judgment, MAUT decision weights represent utilities, and unlike in the case of judgment, these utilities need have no environmental anchor or correct value (instead, it is sufficient merely that certain consistency conditions apply).

As such, the fact that linear-additive models are commonly used to describe both the selection of an action (decision making) and rendering an estimation of an external criterion (judgment) contributes to the difficulty in maintaining a clear distinction between research done on judgment and decision making from a bounded rationality perspective. Models of judgment, that is, of cue-criterion inference, are often sufficient to model decision making or choice in tasks where utility functions do not play an important role and instead, the task boils down to selecting an option solely based on external cue values (e.g., the price and size of a flat panel TV).

Bounded Rationality versus Constrained Optimization. As mentioned previously, Simon himself rejected the idea that bounded rationality referred to cognitively constrained optimization with respect to the structure of a decision environment. Despite this view, it is fair to say that the lion’s share of research performed today in the name of bounded rationality does appeal to a notion of constrained optimization, or

optimization under constraints [17]. For example, Kahneman and Tversky’s Prospect Theory [18] is commonly understood to exist as an illustration of bounded rationality in that it makes provisions (such as framing effects and the lack of a veridical estimation of probabilities) for human limitations in being able to live up to the Olympian ideal of SEU (which Simon originally meant to reject, not merely revise, in his own conception of bounded rationality). However, despite these behavioral provisions, Prospect Theory maintains the general notion that a human decision maker will still seek to optimize to the extent the bounds of cognition (e.g., biases and heuristics, resource limitations) allow.

Some researchers holding true to Simon’s original concept reject the view that any theory of judgment and decision making that appeals to notions of cognitively constrained optimization or maximization should be considered to be a theory of bounded rationality [19] (see *Fast and Frugal Heuristics* and *The Naturalistic Decision Making Perspective*). Despite these views, research programs that construe bounded rationality in terms of constrained optimization to the structure of decision or task environments have flourished in recent decades. Perhaps the most influential has been John Anderson’s research program on “rational analysis” [20]. Characterizing the cognitive theories of the time as a “random set of postulates let loose on the world” and as “bizarre and implausible,” Anderson sought to ground cognitive theory more firmly in the structure of the environment, and the demands the environment makes on cognition. Rational analysis is “an explanation of human behavior based on the assumption that it is optimized somehow to the structure of the environment” (21, p. 471).

Although clearly an approach to modeling cognition as constrained optimization, Anderson [20] nevertheless argued that rational analysis was not incompatible with Simon’s concept of satisficing. However, Simon [22,23] criticized rational analysis for placing too much emphasis on the analysis of the decision environment and not enough emphasis on the knowledge and strategies of the

human decision maker. Whether in response to Simon or not, after developing rational analysis Anderson then turned his attention to complementing rational analysis with a theory of a “cognitive architecture” capable of embodying a scientist’s assumptions of both the declarative (know that) and procedural (know how) knowledge that human cognition brings to a task. This cognitive architecture, adaptive control of thought-rational (ACT-R) [24], has been quite influential in cognitive science and has been used to model a variety of cognitive tasks including decision making, although Belavkin [25] discusses problems associated with the fact that ACT-R does so using expected value maximization, and suggests alternative formulations (also see Ref. 26. Oaksford and Chater [27] provide a discussion of how rational analysis might be brought in line with Simon’s original conception of bounded rationality by integrating aspects of ACT-R and Gigerenzer’s program of fast and frugal heuristics (see *Fast and Frugal Heuristics*). Byrne *et al.* [28] provide one concrete example of this type of integration in their research modeling the decision strategies of experienced airline pilots using ACT-R to implement a set of fast and frugal heuristics.

Coherence versus Correspondence Aspects of Rationality. A third distinction useful for understanding the diverse ways in which the original conceptualization of bounded rationality has been developed in judgment and decision making research concerns Kenneth Hammond’s distinction between coherence and correspondence as alternative benchmarks for assessing rationality [29–31]. Hammond notes that, prior to the pioneering research of Tversky and Kahneman [32], the dominant criterion for assessing the quality of behavior in psychological research was correspondence competence. Correspondence competence refers to whether human judgments (perceptions, assessments, predictions, etc.) of aspects of the external world are empirically accurate. The previous discussion of judgment (as opposed to decision) tasks provides a clear instance of correspondence competence: for example, on the basis of the available information or

cues, does a person render an estimate of the value of an external criterion (say, the distance of a mountain) that is empirically accurate? How accurate is it?

Hammond notes that, in their influential heuristics and biases research program [32], Tversky and Kahneman made a subtle but ultimately extremely important shift of reference in evaluating human behavior away from correspondence competence even while appealing to such competence for explanatory purposes. Tversky and Kahneman (32, p. 1124) wrote:

The subjective assessment of probability resembles the subjective assessment of physical quantities such as distance or size. These judgments are all based on data of limited validity, which are processed according to heuristic rules. For example, the apparent distance of an object is determined in part by its clarity. The more sharply the object is seen, the closer it appears to be. This rule has some validity, because in any given scene the more distant objects are seen less sharply than nearer objects. However, the reliance on this rule leads to systematic errors in the estimation of distance. Specifically, distances are often overestimated when visibility is poor because the contours of objects are blurred. On the other hand, distances are often underestimated when visibility is good because the objects are seen sharply. Thus, the reliance on clarity as an indication of distance leads to common biases. Such biases are also found in the intuitive judgment of probability.

Concerning the final statement in this passage, Hammond (29, p. 30) observes:

But “such biases” are not found in the intuitive judgment of probability. The authors’ error lies in failing to recognize that the “errors” in the two circumstances are very different. In intuitive judgments of the distance of an object, an error occurs when a person’s subjective judgment of distance does not agree with an objective measure of that distance. In the intuitive estimate of a probability, an error occurs when the estimate does not agree with the calculation of a probability from a mathematical formula.

By shifting the criterion against which human judgments are measured from external, empirical ones to those resulting from a

mathematical formula, Hammond notes that Tversky and Kahneman shifted the yardstick by which rationality is measured from empirical accuracy to the ability to be internally coherent in one's reasoning. Why is this distinction important?

The point was made earlier that different research programs and traditions in psychology all claiming to follow, in one way or another, in the footsteps of Simon's bounded rationality have come to quite different evaluations about the competence of human judgment and decision making. Hammond's coherence versus correspondence distinction is useful in organizing the apparently conflicting empirical findings in this research.

As a rough cut, research that assesses bounded rationality from a coherence perspective, against yardsticks of probability theory and SEU theory (both theories solely of how to be internally consistent, *not* empirically accurate) often tend to find human cognition frail and wanting. In contrast, research that assesses bounded rationality from the perspective of empirical accuracy (see as in *Fast and Frugal Heuristics* and *The Naturalistic Decision Making Perspective*), generally paint a much more optimistic picture of bounded rationality. If Simon was correct that no decision maker can truly apply the normative theories created to ensure internal coherence as a criterion for rational behavior, perhaps we should not be surprised that, when it comes to assessing people instead on their empirical success, that is, on their correspondence competence, they fare much better indeed.

CONCLUSION

The origins of bounded rationality in the pioneering research of Herbert A. Simon have been presented, and the influence of these original ideas have been traced forward to examine how they have influenced a wide variety of contemporary lines of psychological research on both the capabilities and mechanisms of human judgment and decision making. Perhaps not surprisingly, the quality of behavior produced by bounded rationality appears to be higher in tasks for which the

concept was invented (decision making under pressure and the realistic constraints of life) than in tasks for which our normative models are restricted to achieving internally coherent thought, rather than empirically adaptive behavior.

DECISION MAKING WITH PARTIAL PROBABILISTIC OR PREFERENCE INFORMATION

LUIS V. MONTIEL
J. ERIC BICKEL
The University of Texas, Texas,
USA

INTRODUCTION

Mathematical models often require the use of epistemological probabilities to account for possible states of the world. In general, we could think of such probabilities as an expression of our beliefs, or as a consequence of reasoning based on specific information. In any case, the complete characterization of epistemological probabilities is difficult, and in some cases is beyond the reach of the decision maker (DM). An analogous problem can be observed in the elicitation of utility and value functions [1], where the specification of the parameters is subject to the DM's attitude. In this article, we present a general procedure to solve decision problems under uncertainty when the epistemological probabilities or utility functions are incompletely specified.

The problem of interest to the DM is to find a unique optimal alternative among all possible choices given the underspecified probabilities [2, 3] or utilities [4–8]. However, such under specification generates scenarios where two or more alternatives are potentially optimal. Hence, the challenge is to determine up to what degree an alternative is optimal.

The methods presented by Yu [9], Sarin [10], White *et al.* [11], Moskowitz *et al.* [12] and Greco *et al.* [8] excluded dominated alternatives by means of solving a series of optimization problems. Others such as [4, 5] and [6] use similar optimization formulations to extract information from the set of possible weights. However, the final outcome of all of these methods is often a set of potentially

optimal alternatives, any of which can be optimal under some particular scenario. Hence, these methods can fail to recognize the single best alternative within the set, leaving the DM with no clear route of action.

In contrast to the previous methods, Refs 3, 7 and 13 proposed approaches in which each alternative is evaluated according to its region of optimality. These methods rely on the analysis of the volume of the relative interior of the set of all possible probabilities (or weights) and provide information about the level of optimality of each alternative according to the portion of the volume for which each alternative is the best, second best, and so on. Hence, it is possible to provide guidance to the DM based on the fact that two potentially optimal alternatives can have different degrees of optimality.

In particular, this article reviews the joint distribution simulation procedure (JDSIM) proposed by Montiel and Bickel [13]. This procedure explores the volume of the relative interior of any arbitrarily constrained polytope without the need to compute the limits of an n -dimensional integral. Hence, it is possible to use the concepts developed by Charnetski [3], and Lahdelma and Salminen [7] beyond the trivial case of the unit simplex, and apply scores of optimality in highly constrained problems in large dimensional subspaces, which was computationally intractable with previous techniques.

The remainder of this article is organized as follows. The section titled “The Truth Set” presents a review of JDSIM basic concepts to encode partial information and develops the constraints and the sampling methodology to evaluate multiple alternatives. The section titled “Alternatives and Truth Sets” provides an overview of the tools to analyze different alternatives when there are neither dominant nor dominated alternatives. The section titled “Example of Index and Regions

of Optimality” presents an example to illustrate the use of JDSIM, and the section titled “Conclusions” concludes and describes possible lines of future research.

THE TRUTH SET

As described by Howard [14], a decision requires three main elements: a set of alternatives ($\mathbf{J}$), a preference rule often defined by a utility function $u(\cdot)$, and information, which is the source of the epistemological probabilities. We will concentrate on the epistemological probabilities. However, as shown by Charnetski [3], Charnetski and Soland [15], and Lahdelma and Salminen [7], the problem of incompletely specified utility functions is mathematically equivalent. For example, Refs 16 and 1 presented applications for joint probability distributions and multi-attribute utility functions, respectively.

In decisions with partial but incomplete information, it is necessary to examine the set of all possible realizations, which we named the “truth set” ($\mathbb{T}$). In the case of epistemological probabilities, that set contains all joint distributions that match the partial beliefs. When $\mathbb{T}$ is defined by linear constraints, that is, the beliefs can be expressed using linear inequalities, the truth set becomes closed, continuous, convex, and

bounded [17]. More precisely, the truth set is defined as: $\mathbb{T} = \{\mathbf{p} | \mathbf{A}\mathbf{p} \leq \mathbf{b}, \mathbf{p} \geq 0\}$, where $\mathbf{A} \in \mathbb{R}^{m \times n}$ is a matrix of constraints, $\mathbf{b} \in \mathbb{R}^m$ is a vector of beliefs, and $\mathbf{p} \in \mathbb{R}^n$ is a joint distribution with n joint elements and subject to m beliefs.

Truth Sets with Partial Information

A simple example will illustrate the effects of partial information. Let V_1 and V_2 be two binary random variables with marginal probabilities $P(V_1 = 1) = p$ and $P(V_2 = 1) = q$. If p and q are unknown, the joint distribution

$$P(V_1 = 1, V_2 = 1) = P_1,$$

$$P(V_1 = 1, V_2 = 0) = P_2,$$

$$P(V_1 = 0, V_2 = 1) = P_3,$$

$$P(V_1 = 0, V_2 = 0) = 1 - P_1 - P_2 - P_3,$$

can be expressed as a non-negative vector (P_1, P_2, P_3) whose elements sum to less than one. Figure 1 shows the truth set when there are no expressed beliefs about V_1 or V_2 . Figure 1a and b present the front and back views of $\mathbb{T}$, where every gray point represents a full joint distribution in the interior of a three-dimensional unit simplex.

As new information is assessed, the truth set is reduced, providing a better understanding of the behavior of the uncertainties. For example, assume that we believe that

Figure 1. Truth set for two binary variables with unknown information.

Figure 2. Truth set for two binary variables with beliefs $p \geq 0.4$ and $0.6 \geq q \geq 0.3$.

$p \geq 0.4$ and $0.6 \geq q \geq 0.3$ for $p = P_1 + P_2$ and $q = P_1 + P_3$. Then, the set of all possible joint distributions is reduced to a new set $\mathbb{T}'$ as shown in Fig. 2, where Fig. 2a and b present the front and back views of $\mathbb{T}'$, which are oriented to facilitate comparison to Fig. 1a and b.

These figures show that the available information is insufficient to specify a unique joint distribution. However, the new constraints reduce the space of possible joint distributions, and possibly reduce the number of potentially optimal alternatives.

Constructing the Truth Set

The truth set can encode any beliefs that are expressed in terms of linear inequalities. A modified version of JDSIM can also include nonlinear inequalities under the condition that $\mathbb{T}$ does not violate the convexity assumption. However, the additional flexibility generates a reduction on the speed of the algorithm. Moreover, most of the reliable information that can be collected from the DM can be expressed in linear inequalities (marginal and pairwise probabilities, moments, preferences, etc.), making the use of nonlinear inequalities an uncommon event. In the following, we present some of the assessment constraints that can be included in $\mathbb{T}$ and refer the reader

to [18], and [13, 19] for a broader overview on assessment constraints.

To simplify the notation, we use the dot notation as follows. We order the random variables as $(V_1, V_2, \dots, V_N)$ for a total of n possible joint events. For each joint event, let $P(V_1 = v_1, V_2 = v_2, \dots, V_N = v_n) = p_{v_1, v_2, \dots, v_n}$, and replace the realization v_i with a “.” whenever we take the sum over all possible outcomes of V_i . For example, if $N = 3$, then $p_{v_1, \cdot, \cdot}$ is defined as in Equation (1).

$$p_{v_1, \cdot, \cdot} = \sum_{i,j} p_{v_1, i, j}, \quad \forall V_2 = i, V_3 = j. \quad (1)$$

Hence, $p_{v_1, \cdot, \cdot}$ represents the marginal probability $P(V_1 = v_1)$, and $p_{v_1, \cdot, v_3}$ represents the pairwise probability $P(V_1 = v_1, V_3 = v_3)$.

Matching Necessary Conditions. To match the necessary conditions, the joint probability mass function (pmf) must sum to one and each probability must be non-negative. We represent these constraints with Equation (2a) and (2b), where the set $\mathbf{V} = \{(i, j, \dots, k) \mid V_1 = i, V_2 = j, \dots, V_N = k\}$ is the Cartesian product of the outcomes of the random variables V_1 to V_N .

$$\sum_{(i, j, \dots, k) \in \mathbf{V}} p_{i, j, \dots, k} = 1, \quad (2a)$$

$$p_{i, j, \dots, k} \geq 0, \quad \forall (i, j, \dots, k) \in \mathbf{V}. \quad (2b)$$

Equation (2a) and (2b) give the necessary and sufficient conditions for $\mathbf{p}$ to be a pmf and are required in all cases. Equation (2a) reduces the dimension of the polytope $\mathbb{T}$ from n to $n - 1$, and Equation (2b) limits $\mathbb{T}$ to the positive orthant.

Matching Marginal and Pairwise Probabilities. Assessments regarding marginal and pairwise belief probabilities can be implemented as Equation (3a) and (3b), respectively. These equations can be extended to cover three-way, four-way, or higher-order joint probability assessments.

$$\sum_{(v_1, i, j, \dots, k) \in \mathbf{V}} p_{v_1, i, j, \dots, k} \geq P(V_1 = v_1), \quad (3a)$$

$$\sum_{(v_1, i, v_3, \dots, k) \in \mathbf{V}} p_{v_1, i, v_3, \dots, k} \geq P(V_1 = v_1, V_3 = v_3), \quad (3b)$$

Matching Moments. When the marginal probabilities are unknown and the random variables take numerical values, it is possible to match beliefs about the moments. For example, if V_1 takes values in $\{v_1^1, v_1^2, \dots, v_1^k\}$ where $v_1^i \in \mathbb{R}$, we can use Equation (4) as follows.

$$\sum_{i=1}^k (v_1^i)^z \cdot p_{v_1^i, \dots, \dots} \geq E[(V_1)^z], \quad (4)$$

where $p_{v_1^i, \dots, \dots}$ is a summation over all joint event probabilities with $V_1 = v_1^i$.

Equation (4) matches the z th moment of V_1 . For $z = 1$, we can match the expected value, and for $z = 2$ we can match the second raw moment. $z = 0$ is simply a restatement of Equation (2a) and the requirement that the probabilities sum to one. Because the outcomes $\{v_1^1, v_1^2, \dots, v_1^k\}$ are known, the constraint is linear in the joint probabilities $p_{v_1, j, \dots, k}$.

Sampling the Truth Set

After characterizing $\mathbb{T} = \{\mathbf{p} | \mathbf{A}\mathbf{p} \leq \mathbf{b}, \mathbf{p} \geq 0\}$ using Equations (2), (3), (4), or any other linear constraint that expresses probabilistic beliefs [17, 18, 20], JDSIM proceeds to create a collection of joint distributions uniformly spread over the volume of $\mathbb{T}$. To sample the interior of the truth set, we use a Markov Chain Monte Carlo procedure named Hit and Run (HR), which was proposed by Smith [21]. This procedure is the fastest-known algorithm to sample the interior of an arbitrary polytope [22]. HR provides a sampling method that allowed us to test problems considerably larger [17] than those considered by Charnetski [3], and Lahdelma and Salminen [7].

HR creates a random grid of joint distributions over $\mathbb{T}$. Hence, each subset of $\mathbb{T}$ of equal volume has approximately the same number of distributions. The algorithm is briefly described below and illustrated in Figure 3. Montiel and Bickel [13] provided more detail regarding this procedure.

Figure 3. Illustration of the sampling procedure in two dimensions.

- Step 1: Set $i = 0$ and select an arbitrary point $\mathbf{p}_i \in \mathbb{T}$.
- Step 2: Generate a set $D \subseteq \mathbb{R}^n$ of directions.
- Step 3: Choose a random direction $\mathbf{d}_i$ uniformly distributed over D .
- Step 4: Find the line set $L = \mathbb{T} \cap \{\mathbf{p} | \mathbf{p} = \mathbf{p}_i + \lambda \mathbf{d}_i, \lambda \text{ a real scalar}\}$.
- Step 5: Generate a random point uniformly distributed over $\mathbf{p}_{i+1} \in L$.
- Step 6: If $i = N$, stop. Otherwise, set $i = i + 1$ and return to Step 2.

ALTERNATIVES AND TRUTH SETS

Dominance and Potential Optimality

When the characterization of the joint distribution is unique and the set of possible alternatives ($\mathbf{J}$) is finite, standard procedure is to find the alternative that maximizes the expected utility, for some utility function $u(\mathbf{x}^j)$ over a vector of attributes $\mathbf{x}^j, \forall j \in \mathbf{J}$. However, in the case of incomplete or partial information, the number of joint distributions is infinite. This generates three possible relevant scenarios related to an alternative $i \in \mathbf{J}$ with respect to $\mathbb{T}$.

Scenario one: alternative i dominates all other alternatives. Then:

$$\forall \mathbf{p} \in \mathbb{T}, \text{ and } \forall j \in \mathbf{J}, \text{ such that} \\ E_{\mathbf{p}}[u(\mathbf{x}^i)] \geq E_{\mathbf{p}}[u(\mathbf{x}^j)], \quad (5)$$

with at least one strict inequality. In this scenario, the DM has no ambiguity in his/her optimal selection, there is only one alternative to be implemented.

Scenario two: alternative i is dominated by at least one other alternative. Then:

$$\forall \mathbf{p} \in \mathbb{T}, \exists j \in \mathbf{J} \text{ such that} \\ E_{\mathbf{p}}[u(\mathbf{x}^j)] \geq E_{\mathbf{p}}[u(\mathbf{x}^i)], \quad (6)$$

with at least one strict inequality. In this scenario, the DM can remove alternative i and reduce the optimal selection problem. This action does not eliminate the ambiguity on the optimality of the rest of the alternatives, it only reduces the size of the problem.

Scenario three: alternative i is a potential optimal alternative. Then:

$$\forall j \in \mathbf{J}, \exists \mathbf{p} \in \mathbb{T} \text{ such that } E_{\mathbf{p}}[u(\mathbf{x}^i)] \geq E_{\mathbf{p}}[u(\mathbf{x}^j)], \quad (7)$$

with at least one strict inequality. This scenario is common in decision problems and provides neither a clear optimal choice nor a reduction of the size of the problem. In this case, we need to apply a procedure to select the best alternative among all potential optimal alternatives.

With the exception of [3] and [7], previous methodologies exploit scenarios one and two by searching for dominant and dominated alternatives by solving different optimization models. However, to study the potential optimal alternatives (third scenario) requires a more detailed understanding of its relation to the truth set.

Index and Regions of Optimality

Basic decision analysis theory shows that for every joint distribution in $\mathbb{T}$, there exists an alternative $i \in \mathbf{J}$ that maximizes $E_{\mathbf{p}}[u(\mathbf{x}^i)] \forall j \in \mathbf{J}$. Hence, we want to know for which subset of $\mathbb{T}$ a potentially optimal alternative is, in fact, optimal. To this purpose, define the set $\mathbb{T}^i = \{\mathbf{p} \in \mathbb{T} | E_{\mathbf{p}}[u(\mathbf{x}^i)] \geq E_{\mathbf{p}}[u(\mathbf{x}^j)] \forall j \in \mathbf{J}\}$ as the region of optimality for alternative i .

The region of optimality provides new relevant information about alternative i . Consider the possible scenarios of alternative i . If i is dominant, then $\mathbb{T}^i = \mathbb{T}$. If i is dominated, then $\mathbb{T}^i = \emptyset$. And if i is potentially optimal, then $\mathbb{T}^i \subset \mathbb{T}$. In the first two cases, the region of optimality provides the same information as would the methodologies cited above. However, in the last scenario, our procedure provides new information about the fraction of the truth set for which an alternative is optimal.

By taking the ratio of the volume of the region of optimality to the volume of the truth set, we can define the index of optimality for alternative i as $I^i = \frac{\text{Vol}(\mathbb{T}^i)}{\text{Vol}(\mathbb{T})}$. The range of the index of optimality is $[0, 1]$, where zero indicates that the alternative is dominated, one indicates that the alternative dominates all others, and values in $(0, 1)$ provide the fraction of $\mathbb{T}$ for which alternative i is dominant.

Hyperplanes and Regions of Optimality

After creating a collection of joint distributions from $\mathbb{T}$, we can cluster all joint distributions for which alternative i is optimal. These clusters are approximations of $\mathbb{T}^i$, and under linearity conditions can be separated by equations of the form $\mathbf{a}^T \mathbf{p}^i \leq \mathbf{a}^T \mathbf{p}^j$ for some $\mathbf{a}^T$, where $\mathbf{p}^i \in \mathbb{T}^i$, $\mathbf{p}^j \in \mathbb{T}^j$, and $i \neq j$.

The vector $\mathbf{a}^T$ represents a hyperplane that separates the distributions in $\mathbb{T}^i$ from the distributions in $\mathbb{T}^j$. In general, the vector $\mathbf{a}^T$ is not intuitive or easy to assess, but it provides a guide for choosing cuts that the DM may find easier to understand. As a result, it can be used to establish questions that, if answered by the DM, can help to differentiate among potentially optimal alternatives with similar indices of optimality. Hyperplanes and regions of optimality provide an important tool in the analysis of potentially optimal alternatives.

EXAMPLE OF INDEX AND REGIONS OF OPTIMALITY

This example assumes that we need to select one alternative among 12 possible options (a_i), and each alternative will return a payoff depending on the state of the world (s_j) as depicted in Table 1. In a typical decision problem, we will assess a probability for each state of the world and choose the alternative with the highest expected value. However, a complete assessment of the joint probabilities is not always possible, and in those situations we need to rely on methods that exploit partial information.

If we assume that there is no information about the uncertainties, then any joint

distribution could be considered valid. However, a better approach is to ask not which distribution should we use to solve the problem, but which alternative is optimal under the largest number of possible discrete distributions, that is, which alternative has the largest index of optimality.

Table 2 shows that, given no information, there are no dominant alternatives ($I^i = 1$) nor dominated alternatives ($I^i = 0$). Hence, any attempt to reduce the problem or to find an optimal alternative will be unsuccessful. In this scenario, a decision needs to be based on the criterion proposed by Charnetski [3], where the best alternative is the one with the largest region of optimality (i.e., index of optimality), which corresponds to alternative a_4 .

Eliciting new information from the DM might cause some of the joint distributions to become inconsistent. This reduction of the truth set generates new regions of optimality that facilitate the selection of a single alternative. For example, assume that as in the section titled “Truth Sets with Partial Information”, we know that $p \geq 0.4$, and that $0.6 \geq q \geq 0.3$. Then, the new indices of optimality are as shown in Table 3.

The index of optimality has revealed that about 72% of the truth set is dominated by two alternatives: a_4 and a_{12} . At this point, if a decision needs to be made, we know that a_4 dominates a_{12} over a larger region of $\mathbb{T}$, which makes it a more suitable choice given what we know.

Figure 4 shows that given the new information, the regions of optimality for a_1 (black), a_2 (dark gray), and a_3 (mid-dark gray) are outside of $\mathbb{T}$ (Bold-dark-solid lines) and can be excluded from the set of

Table 1. Payoffs for Four Possible States of the World under 12 Possible Alternatives

States	Alternatives

**Figure 4.** Truth set for alternatives a_1 (black), a_2 (dark gray), a_3 (mid-dark gray), a_9 (light gray), and a_{11} (mid-light gray) assuming no information. The black straight lines describe the truth set, given the additional information.

potentially optimal alternatives. Moreover, alternatives a_9 (light gray) and a_{11} (mid-light gray) have regions of optimality that have been dramatically reduced.

Given these results, a question of interest for the DM is: Which new information could be helpful to increase or reduce to zero the index of optimality of a_4 ? By choosing the vector $\mathbf{a}^T$ that separates $\mathbf{a}^T \mathbf{p}^i \leq \mathbf{a}^T \mathbf{p}^j$ for all $\mathbf{p}^i \in \mathbb{T}^4$ and all $\mathbf{p}^j \in \mathbb{T}^{12}$, we can find a question that increases or reduces the index of optimality of one of the alternatives. For example, Equation (8) shows the analytical description of the hyperplane that separates the collection of distributions sampled from $\mathbb{T}^4$ and $\mathbb{T}^{12}$.

$$0.3052 \cdot P_1 + 0.2032 \cdot P_2 + 0.4915 \cdot P_3 = 0.2286. \quad (8)$$

We illustrate the regions of optimality of a_4 in light gray and a_{12} in dark gray, separated by a hyperplane represented by a black speckled shade in Figure 5.

Equation 8 might seem unintuitive to the DM. However, it is possible to find approximations to $\mathbf{a}^T$ that are easy to interpret. For example, we can approximate Equation 8 by Equation 9:

$$\frac{1}{3} \cdot P_1 + \frac{1}{3} \cdot P_2 + \frac{1}{3} \cdot P_3 = 0.2234, \quad (9)$$

Figure 5. Truth set for alternatives a_4 (light gray) and a_{12} (dark gray), considering the additional information, and the hyperplane that separate both regions (black speckled shade). The black straight lines describe the truth set, given additional information.

which can be interpreted as $P(V_1 = 0, V_2 = 0) = 0.3299$. Hence, if we can assess whether $P(V_1 = 0, V_2 = 0) \geq 0.3299$ or $P(V_1 = 0, V_2 = 0) \leq 0.3299$, we could eliminate alternative a_4 ($I_{a_4} = 0$) or increase its index of optimality to $I_{a_4} = 0.535$. This procedure can be repeated until the DM is comfortable choosing the alternative that is optimal for most of the valid joint distributions, even if there is no dominant alternative.

CONCLUSIONS

The analysis of decisions where alternatives are neither dominant nor dominated requires a deep understanding of the interactions among regions of optimality. In this article, we explained how JDSIM can be used to explore and understand such interactions when partial information is available.

JDSIM can be applied to address incompletely specified joint distributions or to analyze the parameters of multi-linear utility functions when the DM is able to provide only partial assessments. This sampling procedure is applicable to high-dimensional complex problems and is a simple and efficient technique.

Future research needs to address the process in which elicitation information is gathered, in particular, an implementation of

JDSIM that can use sampled collections to optimize the sequence of questions to be asked will represent an important advance for practitioners.

DECISION PROBLEMS AND APPLICATIONS OF OPERATIONS RESEARCH AT MARINE CONTAINER TERMINALS

Engineering, University of
Washington, Seattle, Washington

INTRODUCTION

The freight transportation system has played a significant role in boosting the growth of international trade and economic prosperity. Among the freight transportation modes, maritime transportation accounts for two-thirds of world trade in metric tonnes [1]. In particular, container transportation has become the predominant mode of nonbulk world cargo traffic, accounting for over 90% of the world's nonbulk deep-sea cargo [2]. Some routes, especially between economically strong and stable countries, are containerized at close to 100% [3].

Containers were first used for international transport of marine freight in the mid-1950s. Using containers has a number of advantages over conventional bulk shipping, which includes less need for product packaging; more protection of goods against weather, pilferage, and damage; and higher productivity of the entire goods movement chain [4]. They allow for faster handling due to increased automation and reduced labor requirements as their contents do not need to be unpacked at each point of transfer [4]. These benefits are realized because to some extent container dimensions have been standardized. Containers are measured by TEU (twenty-foot-equivalent unit), which refers to the volume held by one container with a length of 20 ft. The container with a length of 40 ft or 45 ft represents two TEUs. Domestic containers in the United States are wider

and longer, measuring 53 ft in length. Owing to these differences in container size and relative pricing, many goods imported into the United States are still transferred from marine containers to the larger US domestic containers at US ports.

Container terminals are important intermodal interfaces between maritime and inland transportation. Their main function is to facilitate the transfer of containers between marine vessels and inland modes such as rail and truck transportation. In addition, some container terminals serve ship-to-ship transfers or transshipments. Container terminals are large, interdependent, and complex systems, with many processes and activities involved in container movements. Figure 1 illustrates a container terminal from Poland and shows the ship berths, waterside container cranes, (called *quay cranes* [QC]), and container storage areas. The smaller orange cranes within the container stacks (called *yard cranes*) are used to retrieve and store containers and serve inland transportation vehicles.

Growing global trade and container traffic has put pressure on container terminal operations and inland freight distribution [5]. Consequently, older container terminals are facing increasing congestion problems since they are generally located in urban areas with little available land for physical expansion or inland transport network improvement. Meanwhile, newly constructed container terminals increase the competition between ports. In addition, container terminals have been under pressure to reduce the air quality impacts of their operations.

These issues have attracted the attention of the academic community, which has used operations research techniques, simulation models, and analytical models to improve terminal operations. Terminals rely on many operational models and analyses to support their improvements and allow for increased cargo volumes. This article provides a brief introduction to container terminal operations, but emphasizes the decision

Figure 1. Baltic container terminal, Gdynia, Poland (http://portaid.com/html/bct_photo.html).

problems and applications of operations research in the marine terminal setting. A few formulations and solution algorithms are also presented. This introductory article does not examine the complexity of these formulations or their objectives.

AN OVERVIEW OF CONTAINER TERMINAL OPERATIONS

Container terminals can be viewed as open systems of container flow with two external interfaces [4]. The two interfaces are the landside, where containers arrive and depart by trucks or trains, and the quayside, where containers are unloaded from and loaded onto

ships. Containers are temporarily stored in the container yard facilitating the decoupling of quayside and landside operations [4]. Figure 2 is a schematic of a container terminal illustrating its system components.

Import containers flow through the terminal in several steps. When a ship arrives at the terminal, it is allocated to a berth, and quay cranes are assigned to move the import containers off the ship. Next, the unloaded containers are transported from quay cranes to the storage yard. For export containers upon arrival, the terminal transportation vehicle drops off the container directly, or a piece of yard handling equipment facilitates taking the container off the vehicle, and stores it on the yard. The import containers

Figure 2. A schematic of container terminal [4].

Figure 3. Wheeled operation at container terminals [7].

may be stored for some length of time and then are retrieved from the yard and transferred to other modes such as trucks, trains, or barges to depart from the terminal [6]. The export containers flow in a reverse direction—they arrive by other modes, such as trucks or trains; are stored in the yard; and depart by container ships. At some terminals, storage time in the terminal has been reduced by improved coordination in marine vessel and truck or rail scheduling; however, in most terminals containers are still stored temporarily.

Containers are either stored on a chassis or on the ground at container yards. In chassis or wheeled storage, the container is stored with the chassis as a unit (Fig. 3).

This method of storage allows for easy and fast transfer of containers and reduces labor requirements, but it requires a larger terminal area to store the same number of containers when compared to grounded storage. Wheeled storage is used in US terminals with large terminal areas and at relatively high labor costs. With grounded storage, containers are stored directly on the ground, without a chassis, and may be stacked on top of each other. Containers are moved in and out of stacks by yard handling equipment (Fig. 4). Ground stacking reduces the terminal area requirements, but requires more handling effort and increases transaction time for a truck to retrieve a container. This storage method is popular at European

Figure 4. Ground stacking of containers at a container yard (<http://ports.co.za/admin/large/image-303.jpg>).

Figure 5. Super-PostPanamax cranes in Port of Rotterdam (http://upload.wikimedia.org/wikipedia/commons/0/0b/Portainer_%28gantry_crane%29.jpg).

and Japanese ports, the Port of Hong Kong, and US terminals where land is scarce. Grounded storage methods increase the complexity of terminal operations because containers are not independent—accessing one container may require moving others.

Terminal Equipment

The material handling equipment at container terminals can be classified into two types: cranes and transporters.

The two types of cranes used are quay cranes (Fig. 5) that load and unload ships, and yard cranes (Fig. 4) that stack and handle containers on the yard. The two main components of a crane are a supporting framework that can traverse the length of a quay or yard, and a moving platform called a *spreader*. The spreader can be lowered down to access a container and it locks on to the container's four locking points. Cranes normally lift a single container at a time. However, some cranes are able to pick up four or more TEUs.

There are two types of quay cranes namely, single-trolley and dual-trolley

cranes. The trolley travels along the arm of a crane to lift the containers with its spreader. Dual-trolley cranes are expected to produce twice as many moves per hour as conventional cranes, though neither achieves theoretical capacity in practice. Steenken *et al.* [4] noted “the technical performance of a quay crane is in the range of 50–60 moves/h, while in operation is in the range of 22–30 moves/h.” In Singapore, robotics has allowed a single operator to operate many cranes, but this is not yet common.

Three types of yard cranes are used in container terminals: rubber-tired gantry cranes (RTGs, Fig. 4); rail-mounted gantry cranes (RMGs); and overhead bridge cranes (OBC). An RTG is a mobile gantry crane, which runs on rubber-tires and capable of straddling at least 6 rows and stacking 4–7 containers high [8]. An RMG is less flexible and runs on fixed tracks. The largest RMG is able to straddle 12 to 20 rows and can stack up to eight high [8]. An OBC is a type of crane with the trolley traveling along a horizontal beam that is mounted on two parallel and elevated

Figure 6. Straddle carrier (http://en.wikipedia.org/wiki/File:Containerlift_straddle_carrier.jpg).

runways. The operation of the OBC is limited to the area between the runways [7]. The technical performance of gantry cranes is approximately 20 moves/h.

Transporters are used for moving containers within the storage yard and between the storage yard and the marine vessel. The two types of transporters used are passive transporters that must be loaded or unloaded by other equipment and transporters that are capable of lifting containers by themselves. Passive transporter vehicle types include yard trailers, multiload yard trailers, and automated guided vehicles (AGV). An AGV is driven by an automatic control system instead of a driver and follows guided paths electronically stored in the memory of the control system. Transporters with lifting abilities include straddle carriers (SC, Fig. 6); reach stackers; and forklifts. SCs have been widely used and are able to stack up to four containers. Automated SCs have also been developed, and are successfully being used at some terminals such as the Patrick container terminal in Brisbane.

While a considerable literature exists regarding performance measurement and

comparing marine terminal performance [9], the remainder of this article focuses on decision problems and applications.

CONTAINER TERMINAL DECISION PROBLEMS AND THE APPLICATION OF OPERATIONS RESEARCH MODELS

Decision problems in container terminals can be classified into three types: design problems, operational planning problems, and real-time control problems [10]. Design decisions are made in the initial planning stages with regard to terminal configuration including determining the number and type of material handling equipment, the terminal layout (or placement of equipment), and the degree of automation of handling equipment. An important related issue is the estimation of various performance measures of the intended terminal configuration to compare and evaluate different terminal designs [9]. Operational planning is performed after the terminal has been designed but before operation actually happens, and it is performed to allocate resources for handling activities to maximize the efficiency of terminal operations. The key resources include berths, quay cranes, yard cranes, and the terminal area. Real-time control problems match handling tasks with the required resources and develop detailed operational schedules and plans for day-to-day operating decisions.

The following sections describe important decisions that are supported by operations research techniques, and must be made to address the design, operational, and real-time control problems faced by marine terminals as they grow and improve. We build upon four previous articles that have summarized or described operations research work in marine terminals, namely, Vis and de Koster [6], Steenken *et al.* [4], Kim [11], and Stahlbock and Vos [12].

Quayside Decision Problems

This section addresses the three types of decision problems as they relate to quayside, or waterside operations of a container terminal. In terms of design problems, this

section considers the type of quay cranes and transporters to be used in a terminal. Then, the section examines the use of operations research models to address relevant operational planning problems, including the berth allocation, quay crane allocation, discharge and load sequencing of containers, and determination of number of transporters needed. Finally, transporter allocation, scheduling, and routing problems, which are optimized in real time during terminal operations, are discussed.

Determination of Quayside Equipment Types. Terminal design is constrained by the amount of available shoreline with good marine and land access, and is dependent on the characteristics of the port, the degree of automation desired, traffic volume, relevant regulations, and the costs and benefits of the design. Choosing specific types of equipment depends on the technical characteristics of the equipment. For example, automated handling equipment requires a large initial investment but has lower operating costs, while manned equipment is less expensive initially but requires significant labor, contributing to higher operating costs. This choice should be made by performing a feasibility and economic analysis on various types of equipment [13]. The equipment choice also depends on the design of the area in which the equipment operates. Vis and Harika [13] used simulation to examine the effect of using automated lifting vehicles (ALV) and AGV on the unloading times of a ship. Their work only considered the container unloading process. They found using AGVs or ALVs does not impact the unloading time of a ship. However, 38% more AGVs are required than if ALVs are used to minimize the ship unloading time. They concluded, by observing only purchasing costs of equipment, ALVs are the less expensive option than AGVs since fewer are required. Their sensitivity analysis indicated the layout of the terminal and the technical aspects of equipment (quay crane and vehicle) impact the number of vehicles required and thus the choice of equipment.

Berth Allocation, Quay Crane Allocation, and Scheduling. Berth allocation is the

assignment of quay space and service time to vessels that have to be unloaded and loaded at a terminal. After the berth plan is generated, quay cranes need to be allocated to ships and the ship bays to perform all required transshipments. This process is referred to as *quay crane allocation*. The third step, called *quay crane scheduling*, is to determine the sequence and time schedule of discharging and loading operations that the assigned quay cranes will perform for a ship. The three decisions can be made in a sequential fashion and they are interrelated. For example, the number of quay cranes assigned to a vessel affects the berth duration of the vessel. However, because of the complexity involved in ship operations planning, most academic researchers decompose the problem into these three steps. An overview of berth allocation and quay crane scheduling problems is given in Bierwirth and Meisel [14].

The berth allocation problem (BAP) assigns a berthing position and a berthing time to each vessel, to optimize a given objective function [14]. A graphical representation of a berth schedule for five vessels is shown in Fig. 7a. The vertical axis represents positions along the quay, while the horizontal axis represents time schedule. The BAP solution can be represented by rectangles placed between two axes. These rectangles must not overlap with each other for the berth plan to be feasible. Several constraints are involved in berth allocation. Spatial constraints restrict the feasible berthing positions of vessels according to the layout of the quay into berths. Some studies consider a discrete layout, where the quay is partitioned into a number of sections, called *berths*. Only one vessel can be served at each single berth at a time. Other studies use a continuous layout, in which the quay is not partitioned and vessels can berth at any point within the boundaries of the quay [14]. Berth planning is more complicated for a continuous layout than for a discrete layout, but the quay space can be better utilized. Other constraints should also be considered. For example, the vessels must be berthed at positions with sufficient water depth. The general goal of berth planning is to provide fast and reliable services of vessels.

Figure 7. Space-Time representation of a berth plan (a), assignment of cranes to vessels (b) [14].

Common objectives include minimizing the sum of the waiting and handling time of vessels, minimizing the maximum amount of quay space used at any time, minimizing the workload of terminal resources, and minimizing the number of vessels rejected for service at a terminal.

The dynamic berth assignment problem in the public berth system was studied in Imai *et al.* [15]. This dynamic problem took into account ships that have already arrived and those ships that have not arrived at the time of planning but will arrive at some time later during the planning horizon. The problem was formulated as a mixed integer programming model. The model objective is to minimize the sum of waiting time for berth availability in addition to the handling time spent at the berth, assuming the ship handling time depends on the berth it is assigned and the berths are discrete. A heuristic procedure employing the subgradient optimization procedure was developed based on the Lagrangian relaxation of the original problem. Computational experiments showed that the proposed algorithm is adaptable to real-world problems. The dynamic berth allocation problem with a continuous quay space was also explored in Imai *et al.* [16], and solved using a heuristic algorithm extended from the method developed for discrete BAP [15]. The continuous BAP was addressed by Kim and Moon [17] using a different solution approach. The objective

function of their research problem is to minimize the costs from the delayed departures of vessels and the additional handling costs from deviations of the berthing position from the best location. They suggested a simulated annealing algorithm based on the properties of the optimal solution that is able to find near-optimal solutions.

Quay crane allocation has three specific requirements: a set of specific cranes must be assigned to a vessel, the number of assigned cranes is unchangeable throughout the service process, and a minimum number of cranes serving the vessel throughout the whole process can be prescribed [14]. Figure 7b shows an example of allocating cranes to vessels for fulfilling all the required container transfers. In practice, quay crane allocation is not a difficult problem and has received little attention on its own in academic research. Owing to its impact on ship handling time; however, crane allocation has been studied as a problem integrated with berth allocation. Imai *et al.* [18] addressed the simultaneous berth and crane allocation problem at a multiuser container terminal. This work assumed that berth space is discrete, ship handling does not begin until the required number of cranes is available, and a crane cannot move from one berth to another via other berths if they are engaged in ship handling. A mathematical formulation for this integrated problem was developed to minimize the total ship service time. A genetic algorithm-based

Figure 8. A partial example of ship stowage plan [19].

(GA) heuristic was developed to find an approximate solution for this problem. The two decision making procedures, BAP and quay crane allocation problem (CAP), are constructed one-by-one in an iteration of the entire GA solution procedure. In the BAP phase, the ship-to-berth allocation is determined; given that allocation, in the CAP phase the feasibility of ship service schedule is checked, and the cranes are scheduled by being assigned to ship handling tasks in sequence across all berths. The experimental results showed that the proposed heuristic is able to solve this terminal operation problem sufficiently.

The scheduling goal of the quay crane (QC) is to determine the sequence of discharging and loading operations a QC will perform to minimize the completion time. The two constraints important in this problem are that the container discharging operation must precede the loading operation if performed at the same ship-bay, and the quay cranes cannot cross over each other since they are on the same track. This problem is similar to a minimum makespan scheduling problem with parallel identical machines and precedence constraints, but involves more constraints. The ship stowage plan is required as the input information, and tasks to be

scheduled on a QC can be defined based on bay areas, single bays, container groups, or individual containers. A task defined based on bay areas consists of all the container loading and unloading operations within a certain area of the bays. A task defined based on single bays consists of all the operations in a bay. A task defined based on groups refers to a group of containers stored in adjacent slots of a bay with the same attribute, for example, those containers with the same destination. Lastly, the task defined based on individual containers refers to the operation of a single container [14]. An example of a ship stowage plan used to construct the crane schedule is provided in Fig. 8, which consists of four cross-sectional views, each corresponding to a ship-bay and labeled with odd numbers from 1 to 7. This figure shows four groups of containers to be discharged from the ship bays, and four groups of containers to be loaded into the ship. In Kim and Park [19] the tasks are defined based on container groups (Fig. 8); and several constraints are considered in addition to those mentioned above: tasks on a deck must be performed before tasks in the hold of the same ship-bay when a discharging operation is performed in a ship-bay; the loading operation in a hold must precede the loading operation

on the deck of the same ship-bay; and certain pairs of tasks cannot be performed simultaneously when their locations are too close to each other to avoid crane interference. They formulated the quay crane scheduling problem as a mixed integer programming model and proposed a branch and bound method to obtain the optimal solution, and also suggested a greedy randomized adaptive search procedure to overcome the computational difficulty of the branch and bound method. Quay crane scheduling problem was also addressed by Lee *et al.* [20] using GA. Different from Kim and Park [19], they defined the tasks based on the ship bays.

There has been research to consider the relaxation of the assumption that the discharging operations must occur prior to loading operations. This research identifies a sequence of containers to be handled assuming that loading and discharging operations occur simultaneously. This operation is referred to as *double cycling*. Goodchild and Daganzo [21] formulated this problem as a job scheduling problem with precedence constraints and compared the performance of a greedy algorithm to the optimal solution and found that the results were insensitive to the operating strategy. In another work Goodchild and Daganzo [22] used queueing analysis to examine the implications of double cycling for other aspects of terminal operations, for example, the impact on the need for yard cranes and storage areas.

Operational Planning and Real-Time Decisions Related to Transportation Equipment. One of the operational planning problems related to transportation equipment is in determining the number of transporters required to support ship loading and unloading operations. A sufficient fleet of transporters are needed to avoid quay crane waiting during the ship unloading and loading process, but too many transporters will cause yard congestion and increase cost. This transportation fleet sizing problem at container terminals has been explored by Kang *et al.* [23]. The container unloading process was examined and decomposed into the following four stages:

1. movement of the empty yard truck from yard to berth;
2. truck loading process at the berth;
3. movement of a loaded truck from the berth to yard; and
4. truck unloading process at the yard.

By considering yard trucks as the customers of the queue system, a cyclic queue model was developed to evaluate the steady-state performance of the terminal fleet, and such performance is employed to determine the optimal fleet size which minimizes the terminal cost (operating cost of all handling equipment) and satisfies the terminal throughput requirements. This cyclic queue model can yield the optimum fleet size for long-term operation. To facilitate terminal operators managing fleet in real time, they also proposed a Markovian decision process (MDP) model by considering the stochastic nature of unloading operations. This MDP model could provide dynamic operational policies for fleet management.

The real-time control problem allocates containers to vehicles and routes and is referred to as the *yard vehicle dispatching problem* and *routing problem*. Figure 9 shows an example of dispatching and routing vehicles to transport containers between berths and storage areas. This example includes three quay cranes to be served and nine container stack points in the yard. Two tours are generated to connect cranes and stack points. For vehicle types that are unable to lift containers by themselves, direct transfer of containers to and from quay cranes is required, and there is a delay if a queue forms in front of the quay crane, or when no vehicle is available and the quay crane must wait to release a container. The objective of such problems is to minimize the delay time of quay cranes and the travel time of vehicles. Yard vehicle dispatching and routing are interrelated and have been studied as an integrated problem by some researchers. Nishimura *et al.* [24] addressed the yard assignment and routing problem for both the single-trailer and multitrailer trucks. To improve the productivity of the terminal, a dynamic assignment method was applied,

Figure 9. An example of vehicle dispatching and routing decision [24].

which pools trailers to serve a set of quay cranes instead of assigning each trailer to a specific quay crane. Mathematical formulations were developed to minimize the total travel distance of trucks. The single-trailer problem resembles the single-depot vehicle routing problem with multiple tours from the depot. That problem was reduced to the classical assignment problem whose optimal solution can be readily found. However, the multitrailer version of the problem does not have an efficient exact solution procedure, and the GA was used to find a near-optimal solution. Their research demonstrated that dynamic assignment is superior to the static assignment with regard to the total distance traveled by trailers. It also reduces the fleet size, with 15% saving in fleet cost.

Yard dispatching and routing have also been studied as two independent problems. Kim and Bae [25] examined how to dispatch AGVs by utilizing information about locations and time of future delivery tasks. It was assumed that any AGV is not dedicated to one quay crane. The vehicle scheduling issue was not discussed by ignoring the queueing time of AGVs under yard cranes and the congestion among AGVs on guide paths. The problem was formulated as a mixed integer programming model for assigning optimal delivery tasks to AGVs. Its objective function is to minimize delays in operation of quay cranes and travel time of AGVs, with a higher priority given to quay crane delay. This problem is similar

to a parallel machine scheduling problem with sequence-dependent setup times and precedence constraints among jobs. Since it is nondeterministic polynomial-time (NP-hard), a heuristic algorithm was developed to solve this problem. Their simulation results demonstrated the proposed heuristic algorithm outperforms conventional dispatching rules such as assigning based on the shortest travel time, the shortest distance, or the earliest due date.

Yard Decision Problems

Import and export containers can be temporarily stored in the yard before being loaded onto ships or inland transportation vehicles (Fig. 4). In general, containers are stacked on the ground in several tiers and the entire storage space is divided into rectangular areas called *blocks*. Each block consists of many parallel bays, each bay is composed of several stacks, and each stack stores several containers. An example of a block-and-bay configuration is provided in Fig. 10, with a yard crane employed to perform container delivery and retrieval operations. The maximum number of tiers is limited by the lifting ability of stacking equipment, either straddle carriers or yard cranes, and the structural integrity of the containers themselves. The storage of different types of containers is generally segregated. For example, import containers, export containers, refrigerated containers, and empty containers, each generally have

Figure 10. Container block, bay configuration, and yard crane positioning [26,27].

a designated area. The transfer points of containers are located at the two ends of each container block for a perpendicular layout of blocks (popular at European ports), or a separate lane is dedicated for container transfer beside the block for a parallel layout of blocks (popular at US ports). Since containers are stacked, any container above the desired container must be moved. This process is called *container rehandling*. It is unproductive work and occupies a large amount of total handling time. The number of container rehandles is one metric to measure the operational efficiency of yard operation.

Yard stacking equipment handles containers from both the quayside and landside. They perform two types of operations: picking up import containers delivered by transporters from quayside or export containers delivered by drayage trucks from landside and stacking them into blocks; and retrieving export containers from storage to load onto transporters (for ship loading) or retrieving import containers for loading onto drayage trucks.

Yard design problems include determining yard layout, container block configuration, and the type and number of required

handling equipment, such as yard cranes and straddle carriers. An important operational planning problem concerning the container yard includes storage space allocation for arriving containers. Real-time decisions include assigning tasks to yard handling equipment. This section describes those problems in detail and discusses the application of operations research techniques in addressing them.

Yard Design Problem. The organization of the container yard is crucial for achieving an efficient interface with other processes in the terminal. The type and number of storage and retrieval equipment used in the yard are critical design decisions to ensure yard operations are not the bottleneck of the terminal system. Straddle carriers and yard cranes are the two most popular types of equipment used for storing and retrieving containers. One of the main differences between straddle carriers and yard cranes is span width. A straddle carrier can travel over only a single row of containers, whereas yard cranes can span six or more rows of containers. As a result, straddle carriers need to travel to the end of a row to move to another row while yard

cranes can change rows at any location in the block. The selection between manned straddle carriers and automated stacking cranes (ASC) was discussed in Vis [28]. She performed a simulation study to compare the performance of straddle carriers and ASCs for handling a fixed number of storage and retrieval requests from both the seaside and landside of the terminal. The yard configuration with transfer points located at two block ends was considered, and the total travel time (which includes full and empty travel times, hoisting times, and rehandling times) was used as the performance measure. A sensitivity analysis was also performed to examine the effect of operational aspects (size of workload and arrival patterns of containers) and block layout on the performance of container storage and retrieval equipment. She concluded that if blocks are configured with a width of six containers, the automated stacking crane outperforms the straddle carrier. However, if the block width is increased beyond six to up to nine containers, which will probably reach the maximum span for an ASC, the performance of the SC matches the performance of the ASC.

Kim and Kim [29] discussed how to determine the optimal amount of storage space and the optimal number of yard cranes for handling import containers. The trade-off between the yard space and number of yard cranes was analyzed by considering the associated cost. A terminal operator's cost model was developed to minimize the operational cost of the terminal, yard space cost, and capital cost of yard cranes without considering the level of service for the customers. To evaluate integrated system success, another cost model was developed to minimize the waiting cost of outside trucks as well as the total cost for terminal operation. Solution procedures were suggested to find optimal solutions.

Storage Space Allocation. The method of allocating storage spaces for arriving containers has a significant impact on the turnaround time of ships and drayage trucks because the locations of containers affect the efficiency of delivery and retrieval operations [11]. Common objectives of the space allocation problem are to maximize

storage utilization, minimize rehandles, minimize travel distance, and maximize yard equipment utilization.

The storage space allocation problem was studied in Zhang *et al.* [30] for a complex situation in which inbound, outbound, and transit containers are mixed in the yard. The problem was decomposed into two levels with an overall objective of minimizing the vessel berthing time and maximizing the quay crane throughput rate, and solved using a rolling-horizon approach. The first level determines the total number of containers to be placed in each block to balance the workload of yard cranes and quay cranes. The second level determines the number of containers associated with each vessel to be allocated to each block to minimize the total traveling distance for moving containers between their storage area and ships.

Kim and Kim [31,32] address the storage space allocation problem for import containers. This problem utilized a segregation strategy for allocating containers to empty slots by considering the container's duration of stay at the bottom of stack, and its objective is to minimize the expected total number of rehandles. Different cases were analyzed where the arrival rate of import containers is constant, cyclic, and dynamic. Mathematical models for each case were formulated using stack height and allocation space as decision variables. Problems were solved to optimality based on the Lagrangian relaxation technique.

After a container bay or block with empty slots is already assigned to a specific container group, the next stage of storage space allocation is to determine where to stack an arriving container among a group of available slots. This problem considers the configuration of the container bay to minimize the expected number of container rehandles that occur during the loading operations of a containership or a drayage truck. Kim *et al.* [33] examined the problem of determining the storage location for arriving export containers. They assumed the distribution of container weights is known, and the heavier containers are loaded onto a ship before lighter containers, so rehandles will be incurred if lighter containers are stacked on top of heavier containers at the

Figure 11. An illustration of a yard-bay of blocks with a fixed sequence of pickup [34].

container yard. A dynamic programming model was formulated to determine the optimal storage location, and a decision tree was developed from the set of optimal solutions to support real-time decisions. Kim and Hong [34] studied how to minimize the total number of container rehandles during the pickup operation on the yard by carefully determining the storage location of rehandled containers. They assumed the initial configuration of the container bay is known and the pickup priorities among containers in the bay are also given (Fig. 11). They suggested a branch and bound algorithm to obtain the optimal solution, and then proposed a heuristic rule that estimates the number of future rehandles for the bay to shorten the computational time and find a near-optimal solution.

Task Assignment for Yard Handling Equipment. Two hierarchical problems exist in task assignment decisions: the equipment

deployment problem and the task scheduling problem. Equipment deployment involves the allocation of a certain group of equipment to a specific type of task. Task scheduling includes the assignment of tasks to each piece of equipment and the sequencing of assigned tasks to be carried out [11].

The objective of yard equipment deployment problem is to balance the workload among blocks and has been examined in Cheung *et al.* [35] and Zhang *et al.* [36]. Since block workload varies across different storage areas and time, the handling equipment should be efficiently used to ensure all the required tasks are finished. Zhang *et al.* [36] addressed the dynamic crane deployment problem to find the time and routes of crane movements among blocks so that the total delayed workload in the yard is minimized. The problem was formulated as a mixed integer programming model and solved by Lagrangean relaxation.

Task scheduling for yard handling equipment is performed in real time. It must consider the priorities among tasks to sequence tasks, and also the interference between yard cranes or straddle carriers to estimate the task completion time [11]. The objective of the task scheduling problem is to minimize the completion time of all the tasks (the makespan). An alternate objective is to minimize the sum of transporter waiting time on the yard. The single straddle carrier routing problem during the loading operation of export containers was examined by Kim and Kim [31,32]. The objective is to minimize the total traveling distance of a straddle carrier, and the main constraint considered is that the loading schedule must satisfy the requirements of the work schedule of the quay crane. This routing problem is similar to the network optimization problem, and a two-stage solution procedure was developed. The first stage determines the number of containers to be picked up at each yard-bay during a subtour, and the second stage determines the visiting sequence of yard-bays by the straddle carrier.

The problem of scheduling multiple yard cranes in a yard zone was examined in Ng [37]. It was assumed that the expected arrival time of yard trailers is given, and the objective is to minimize the sum of yard trailer waiting times in the zone. The inter-crane interference constraint was considered, and the problem was formulated as an integer programming model. Since the problem is NP-complete, a two-phase scheduling heuristic was developed to solve the problem. In the first phase, the multiple-crane scheduling problem is simplified and decomposed into m independent single crane scheduling problems; in the second phase, a job reassignment procedure is used to improve the schedule obtained from the first phase. Computational experiments showed that the heuristic can find effective solutions, which is on average 7.3% above their lower bounds.

Landside Decision Problems

In landside operations at container terminals, containers depart and arrive by trains or drayage trucks. For rail operations, trains

have fixed tracks and transportation equipment is needed to move containers from the storage yard to rail facilities. For drayage truck operations, when trucks arrive at the terminal gate, trucks are directed to container transfer points within the terminal, where the container storage and retrieval equipment unloads a container from truck, or transfers a container from the block to the truck. Large container terminals serve thousands of trucks a day. Owing to the dynamic nature of truck arrivals and high truck volume, truck congestion at terminal gates and in container yards is a problem faced by many container terminals around the world.

This section focuses on the road transport mode (drayage trucking) and describes the design of the terminal's landside connection, the operational planning problem of landside transport, and real-time assignment and scheduling of tasks to serve outside trucks.

Design of the Terminal's Landside Connection. The terminal's landside connection is an important interface between the container terminal operations and on-dock rail and drayage truck operations. One of the crucial decisions related to landside design is whether or not to decouple landside operation from the storage yard operation and allocate a separate area dedicated for container transfers to and from trains and drayage trucks, or to allow these vehicles to physically enter the terminal.

In general, on-dock rail operations require a dedicated zone with a container buffer area alongside the tracks. Container handling equipment such as gantry cranes are deployed to unload and load containers onto trains and terminal transportation equipment such as yard trucks and straddle carriers are needed to transport containers between the storage yard and train loading area.

The majority of container terminals around the world do not setup a separate area for truck operation. Instead drayage trucks drive directly into the storage yard for container transfers. However, some automated container terminals have also been redesigning their terminal layout to

improve the terminal capacity, including setting up a dedicated truck operation area.

One example is Patrick Corporation's container terminal at Port Botany in Sydney, which has changed its terminal layout and designed a semiautomated container exchange facility for container transfers to and from trains and drayage trucks. This change is intended to reduce space requirements and increase the container exchange capacity [38]. A simplified layout of Port Botany is provided in Fig. 12. This exchange facility is equipped with rubber mounted gantry cranes, which perform the container loading and unloading operation for trucks and trains. Straddle carriers transport containers between the exchange area and main storage yard. A detailed layout of this exchange facility is shown in Fig. 13 and includes a Gantry-Road interface (GRI), where the drayage trucks arrive and are served by gantry cranes; a Gantry-Rail interface (GRAI), where the trains are loaded and unloaded; an intermediate stacking area (ISA), where the arrival containers are temporarily stacked before being moved to the storage yard, and the booked import containers are placed for quick transfer by cranes onto trucks or trains; and a Gantry-Straddle interface (GSI), where straddle carriers place import containers or pick up export containers [38].

Landside Transport Planning. After the landside layout is determined, a plan must be made for how to serve drayage trucks. Another relevant issue is the management of empty containers. Empty containers may be returned to the terminal after being emptied at the customers' locations, and are moved from the terminal to export customers' locations for loading when demanded. This practice generates unproductive empty truck trips, and exacerbates terminal congestion. By repositioning empty container depots to inland areas, these empty truck trips may be reduced. Although the empty container repositioning problem extends beyond the physical boundary of container terminal, it is included in this section since it closely relates to landside operations.

Drayage Truck Service Problem. The main objective of this problem is to improve the level of service for drayage trucks and the landside throughput. Different strategies can be used to deal with this problem. Terminals can control the number of trucks entering the container terminal to avoid yard congestion, prioritize certain types of trucks to, sequence trucks for container delivery and receiving operations to minimize the truck delay, or carefully determine the storage location of containers to minimize total number of rehandles and reduce truck transaction time. The last two methods fall into the category of real time control decisions and is discussed in the section titled "Real-Time Control of Landside Operation."

Huynh and Walton [39] discussed how to regulate truck arrivals at container terminals. They determined the maximum number of trucks a terminal can accept into a yard zone within each time window, while satisfying the resource and operational constraints and maintaining a specified target truck transaction time. Their methodology is a combination of mathematical formulation and computer simulation, which identifies a solution beneficial for both the terminal operator and truckers.

Prioritizing the service for containers with a higher priority was discussed in Holguín and Walton [40]. They considered a group of priority systems—locating high-priority containers on special hatches, storing them on chassis, or using automatic equipment identification devices at gates—and assessed the impacts on different users based on computer simulation. They concluded the implementation of priority service significantly improves the performance of high-priority containers without overly penalizing the level of service for low-priority containers or significantly affecting the terminal's operating costs.

Empty Container and Chassis Repositioning Problem. The problems of managing empty containers and container chassis have also been addressed with operations research techniques. Crainic *et al.* [41] developed a framework for minimizing the cost of empty container allocation and distribution using

Figure 12. The layout of Port Botany.

Figure 13. Layout of the container exchange area at Port Botany. (a) elevation and (b) ground plan.

optimization schemes. This work provides a foundation for research into the problem of empty containers—to move goods in a container; an empty container must be closely available in both time and space. When trade is balanced, the empty container can be loaded proximate to the destination of its full contents. When trade is imbalanced, significant repositioning of empty containers is required. In an ideal world, once a container

is emptied it would be moved directly to the closest shipper who requires one. However, due to the complex ownership, insurance, and information-sharing issues, empty containers are often inefficiently repositioned. Crainic *et al.* [41] developed a single-commodity, deterministic optimization model and found a multicommodity, stochastic model to be too detailed to be computationally tractable for large networks.

Figure 14. Container depot repositioning [42].

Figure 15. The problem of empty container movement [43].

Boile [42] looked for ways to reduce empty container movements through repositioning of empty depots, using optimization to identify locations that minimize travel, reducing the number of truck miles traveled (Fig. 14). Smilowitz [43] merges network modeling and optimization, assigning not just vehicles to routes, but also tasks to vehicles, considering both loaded and empty containers in an effort to reduce overall travel in a sample of movements in the

Chicago area. In doing so she can identify assignments that minimize vehicle miles traveled (Fig. 15).

Holguin-Veras and Thorson [44] examined the flow of empty containers using probability models, expanding on earlier work to include both a primary and secondary stop before a truck returns to its depot.

Real-Time Control of Landside Operation. Real-time control problems in landside

operation include determining the sequencing of drayage trucks for container transfer operations in the yard, deciding the storage location of containers following delivery and receiving operations, and scheduling the container transfers in real time to serve drayage trucks. The objectives of this problem include minimizing truck delays, rehandling work, and traveling distance of container handling equipment.

Sequencing trucks for container delivery and receiving operations is discussed in Kim *et al.* [45]. They assumed each truck has its own due time for the container transfer service by a yard crane, and their research objective was to minimize the total delay cost. First, a static sequencing problem was examined in which all the truck arrivals are known in advance, and a dynamic programming model is suggested. Later, a dynamic sequencing problem was considered in which new trucks arrive continuously, and a learning-based method for deriving decision rules is suggested and compared to several heuristic rules by simulation study. They found the learning-based rule outperformed the other sequencing rules including a first-come-first-served rule and a shortest-processing-time rule.

Research to determine the optimal storage location of rehandled containers to minimize the number of container rehandles can be found in Kim and Hong [34] and Zhao and Goodchild [26]. Zhao and Goodchild [26] examined how to reduce container rehandles by using drayage truck arrival information. A heuristic rule was used to find the optimal storage location of rehandled containers based on truck arrival information, and computer simulation was developed to evaluate how the truck information quality and container bay configuration affect the amount of rehandling work. Simulation results demonstrated any amount of truck information is useful for reducing number of container rehandles, and that updating information in real time significantly lowers information requirements. The impact of truck arrival information on yard crane productivity and truck transaction time was further investigated in Zhao and Goodchild [27].

Optimizing operations of a container exchange area (described in the section titled “Design of the Terminal’s Landside Connection”) at Port Botany in Sydney was discussed in Froyland *et al.* [38]. This exchange facility is a complex subsystem of the terminal, where both import and export container flows are handled simultaneously. The control decisions to be made includes scheduling the RMG movements, allocating container positions in the ISA, and allocating the delivery locations for trucks and straddle carriers. Multiple objectives were considered including moving all containers while satisfying time window constraints, ISA capacity limit, and target truck waiting time; minimizing the maximum number of straddle carriers required for moving containers between the main storage yard and the exchange area; and balancing the RMGs utilization. This problem does not address train operations and assumed all the data is known in advance for the entire month. Owing to the complexity of the decision making process, this problem was decomposed into three sequential subproblems and solved using a three-stage algorithm. The first subproblem is to assign all container moves at an hourly level and is formulated as an integer programming model. The second subproblem is to assign import containers to positions in the gantry-straddle carrier interface within each hour and is solved by integer programs. The third subproblem is to assign trucks to GRI positions and export containers to GSI positions, and schedule the precise RMG operations within each hour. Since the exact arrival times of trucks within every hour are unknown, an online algorithm was developed to solve the third subproblem. Computational results demonstrated that the proposed approach can find near-optimal solutions.

SUMMARY

This article introduced container terminal operations and a variety of decision problems that exist in operating their different subsystems (quayside, container yard, and

landside). The operations research methods used to address these problems are demonstrated through identifying examples in the academic literature. Depending on the length of planning horizon, the problems were classified into design problems, operational planning problems, and real-time control problems.

Owing to the complexity of container terminal operations, in almost all cases the many interrelated decisions are decomposed into hierarchical problems to simplify the decision process, and the solution of higher level problems are used as the constraints and inputs for optimizing lower level decisions. The majority of research in this field addressed only single types of material handling equipment or a detailed subproblem in the series of hierarchical problems, while a few studies considered an integrated system and optimized the operation of various equipments simultaneously. Most of the work in this field utilized computer simulation and operations research techniques such as queueing theory and stochastic models, network optimization, and metaheuristic optimization algorithms.

While these tools have had significant impact on terminal operations, future research will advance the state of these models by continuing to integrate subcomponents of the system, building more sophisticated operational research models that sufficiently address terminal complexity. It is a ripe area for future research and the application of operations research techniques.

INTRODUCTION

Decision rule model is a preference model for multiple criteria decision aiding (MCDA) (see [1] for a survey), constructed using the dominance-based rough set approach (DRSA) proposed by Greco *et al.* [2]. According to [3], MCDA aims at giving the decision maker (DM) a recommendation in terms of the best actions (*choice*), in terms of the assignment of actions to predefined and preference-ordered classes (*classification*, called also *sorting*), or of the ranking of actions from the best to the worst (*ranking*). Until the end of the last century, in the practice of MCDA, two major preference models were used: the multiple attribute utility theory (MAUT; see [4] and [5]) and the outranking approach (see [6] and [7]). As the preference models are main drivers of decision aiding, they are also called *decision models*. Building these models requires from the DM a specific preference information that is more or less explicitly related to their parameters, like substitution rates for a value function of MAUT, or discrimination thresholds and importance weights of criteria for outranking methods. Direct elicitation of this information requires a great cognitive effort on the side of the DM. Even if one can reduce this cognitive effort by acquiring indirectly these parameters through a training set

of decision examples, like in some ordinal regression methods [8–10], MAUT and outranking methods are often processing such indirect preference information in a way that is not clear for the DM, such that (s)he cannot see what are the exact relations between the provided information and the final recommendation. Consequently, very often, the decision model is perceived by the DM as a *black box* whose result has to be accepted because the analyst's authority guarantees that the result is "right". In this context, the aspiration of the DM to find good reasons for some decision is frustrated and rises the need for a more transparent methodology in which the relation between the original preference information and the final recommendation is clearly shown. Such a transparent methodology has been called *glass box* [11]. Its typical representative is using a training set of decision examples as the input preference information provided by the DM, and it is expressing the decision model in terms of a set of "if..., then ..." decision rules induced from the input preference information. Examples of such rules are the following:

- "if maximum speed of car x is at least 175 km/h, and its price is at most \$ 12,000, then car x is comprehensively at least medium,"
- "if car x is at least weakly preferred to car y with respect to acceleration, and the price of car x is no more than slightly worse than that of car y , then car x is at least as good as car y ".

From one side, the decision rules are explicitly related to the original information, and from the other side, they give understandable justifications for recommended decisions.

The rules induced from the input preference information provided in terms of

exemplary decisions represent a decision model, which is transparent for the DM and enables his/her understanding of the reasons of his/her past decisions. The acceptance of the rules by the DM justifies, in turn, their use for future decisions.

The induction of rules from examples is a typical approach of artificial intelligence. In this context, rough set theory [12–15] proved to be a useful tool for analysis of vague description of decision situations [16,17]. This description is given as a data table, where rows correspond to objects (actions) and columns to condition and decision attributes. Each row of the data table is a decision example. The aim of rough set analysis is the explanation of the dependence between the values of some decision attributes, playing the role of “dependent variables”, by means of the values of some condition attributes, playing the role of “independent variables”. For example, in a diagnostic context, data about the presence of some diseases are given by decision attributes, while data about symptoms are given by condition attributes. An important advantage of the rough set approach is that it can deal with partly inconsistent examples, that is, objects indiscernible by condition attributes but discernible by decision attributes (e.g., cases where the presence of different diseases is associated with the presence of the same symptoms). Moreover, it provides useful information about the role of particular attributes and their subsets and prepares the ground for representation of knowledge hidden in the data by means of “if..., then ...” decision rules relating values of some condition attributes with values of decision attributes (e.g., “if symptoms A and B are present, then there is disease X ”).

For a long time, however, the use of the rough set approach and, in general, of data mining techniques, has been restricted to classification problems where the preference order of evaluations is not considered. Typical examples of such problems come from medical diagnostics. In this context, symptom A is not better or worse than symptom B , or disease X is not preferable to disease Y . It is, thus, sufficient to consider A as different

from B and X as different from Y . There are, however, situations, where discernibility is not sufficient to handle all relevant information. Consider, for example, two firms, α and β , evaluated for assessment of bankruptcy risk by a set of criteria including the “debt ratio” (total debt/total assets). If firm α has a low value of the debt ratio while firm β has a high value of the debt ratio, then, within data mining and classical rough set theory, α is different (discernible) from β with respect to the considered attribute (debt ratio). However, from the viewpoint of preference analysis and, say, bankruptcy risk evaluation, the debt ratio of α is not simply different from the debt ratio of β but, clearly, the former is better than the latter.

The basic principle of the classical rough set approach (CRSA) and data mining techniques is the following *indiscernibility principle*: if x is indiscernible with y , that is, x has the same characteristics as y , then x should belong to the same class as y ; if not, there is an inconsistency between x and y . According to this principle, if a patient has symptom A and disease X while another patient has symptom B and disease Y , there is not any inconsistency and one can draw a simple conclusion that symptom A is associated with disease X , while symptom B is associated with disease Y .

In multiple criteria decision analysis, indiscernibility principle is not sufficient to convey all important semantics of the available information. Consider again the above two firms: α having a low value of debt ratio and β having a high value of the debt ratio. Suppose that evaluations of these firms on other attributes (profitability indices, quality of managers, market competitive situation, etc.) are equal. Suppose, moreover, that firm α has been assigned by a DM to a class of higher risk than firm β . According to the indiscernibility principle, one can say that α and β are discernible, and it follows that low debt ratio is associated with high risk while high debt ratio is associated with low risk. This is contradictory, of course. The reason is that, within multiple criteria decision analysis, the indiscernibility principle has to be replaced by the following *dominance principle*: if x dominates y , that is, x is at least

as good as y with respect to all considered criteria (condition attributes), then x should belong to a class not worse than the class of y (class assignment by decision attribute); if not, there is an inconsistency between x and y . Applying the dominance principle to α and β , one can state an inconsistency between their debt ratio and the risk of their bankruptcy, which leads to a paradoxical conclusion that the lower the debt ratio is, the higher will be the risk of bankruptcy.

For this reason, Greco *et al.* [2, 18, 19–21] have proposed an extension of rough set theory based on the dominance principle, which permits to deal with MCDA problems. This innovation is mainly based on substitution of the indiscernibility relation by a dominance relation in the rough approximation of decision classes. An important consequence of this fact is a possibility of inferring from exemplary decisions the preference model in terms of decision rules being logical statements of the type “if..., then...”. The separation of certain and doubtful knowledge about the DM’s preferences is done by distinction of different kinds of decision rules, depending whether they are induced from examples consistent with the dominance principle or from examples inconsistent with the dominance principle. The latter rules are very important because they represent situations of hesitation in the DM’s expression of preferences.

This is to say that, using a properly modified technique of artificial intelligence, one can construct a preference model in form of decision rules, by inducing them from exemplary decisions. Such a preference model has some interesting properties: it is expressed in a natural language without using any complex analytical formulation, its interpretation is immediate and does not depend on technical parameters, it is often using only a subset of the considered attributes in each rule, and, finally, it can represent situations of hesitation, typical for a real expression of preferences. The decision rule preference model is, therefore, a new approach to MCDA, which becomes a strong alternative for MAUT and outranking methods.

Dominance-Based Rough Set Approach (DRSA)

Criteria and the class assignment considered within DRSA correspond to the *condition attributes* and the *decision attribute*, respectively, in the CRSA [12, 13, 16]. Different from the CRSA, in DRSA, we are considering criteria that are condition attributes with value sets ordered according to decreasing or increasing preference.

Let us consider the set of n criteria $F = \{g_1, \dots, g_n\}$, the set of their indices $I = \{1, \dots, n\}$, and a finite universe of objects (actions, solutions, and alternatives) U such that, without loss of generality, $g_i : U \rightarrow \mathbf{R}$ for each $i = 1, \dots, n$, and, for all objects $x, y \in U$, $g_i(x) \geq g_i(y)$ means that “ x is at least as good as y with respect to criterion i ”, which is denoted as $x \succsim_i y$ (observe that in case of a criterion g_i that, like the price of a car, is decreasing with respect to the preferences, it is enough to multiply its values by -1 to get again a criterion increasing with respect to the preferences). Therefore, we suppose that $\succsim_i$ is a complete preorder, that is, a strongly complete and transitive binary relation, defined on U on the basis of evaluations $g_i(\cdot)$. Note that, in the context of multiobjective optimization, g_i corresponds to an objective function. Furthermore, we assume that there is a decision attribute d that makes a partition of U into a finite number of decision classes, called *classification*, $\mathbf{Cl} = \{\text{Cl}_1, \dots, \text{Cl}_m\}$, such that each $x \in U$ belongs to one and only one class Cl_t , $t = 1, \dots, m$. We suppose that the classes are preference ordered, that is, for all $r, s = 1, \dots, m$, such that $r > s$, the objects from Cl_r are preferred to the objects from Cl_s . More formally, if $\succsim$ is a *comprehensive weak preference relation* on U , that is, if for all $x, y \in U$, $x \succsim y$ reads “ x is at least as good as y ”, then we suppose

$$[x \in \text{Cl}_r, y \in \text{Cl}_s, r > s] \Rightarrow x \succ y,$$

where $x \succ y$ means $x \succsim y$ and *not* $y \succsim x$. The above assumptions are typical for consideration of a multiple criteria classification problem (also called *ordinal classification with monotonicity constraints*).

In DRSA, the explanation of the assignment of objects to preference-ordered decision classes is made on the basis of their evaluation with respect to a subset of criteria $P \subseteq I$. This explanation is called *approximation* of decision classes with respect to P . Of course, the most commonly considered case is $P = I$. In order to take into account the order of decision classes, in DRSA, the classes are not considered one by one, but, instead, unions of classes are approximated: *upward union* from class Cl_t to class Cl_m , denoted by $Cl_t^{\geq}$, and *downward union* from class Cl_t to class Cl_1 , denoted by $Cl_t^{\leq}$, that is:

$$Cl_t^{\geq} = \bigcup_{s \geq t} Cl_s, \quad Cl_t^{\leq} = \bigcup_{s \leq t} Cl_s, \quad t = 1, \dots, m.$$

The statement $x \in Cl_t^{\geq}$ reads “ x belongs to at least class Cl_t ”, while $x \in Cl_t^{\leq}$ reads “ x belongs to at most class Cl_t ”. Let us remark that $Cl_1^{\geq} = Cl_m^{\leq} = U$, $Cl_m^{\geq} = Cl_m$, and $Cl_1^{\leq} = Cl_1$. Furthermore, for $t = 2, \dots, m$, we have

$$Cl_{t-1}^{\leq} = U - Cl_t^{\geq} \quad \text{and} \quad Cl_t^{\geq} = U - Cl_{t-1}^{\leq}.$$

For example, in multiple criteria classification of cars, the considered cars are the objects evaluated on such criteria as maximum speed, acceleration, price, and fuel consumption, and they are to be assigned to one of three classes of overall evaluation: “bad”, “medium”, and “good”. Then, the upward unions are: $Cl_{\text{medium}}^{\geq}$, that is the set of all the cars classified at least medium (i.e., the set of cars classified as medium or good), and $Cl_{\text{good}}^{\geq}$, that is the set of all the cars classified at least good (i.e., the set of cars classified as good), while the downward unions are: $Cl_{\text{medium}}^{\leq}$, that is the set of all the cars classified at most medium (i.e., the set of cars classified as medium or bad), and $Cl_{\text{bad}}^{\leq}$, that is the set of all the cars classified at most bad (i.e., the set of cars classified as bad). Notice that, formally, also $Cl_{\text{bad}}^{\geq}$ is an upward union and $Cl_{\text{good}}^{\leq}$ is a downward union; however, as bad and good are extreme classes, these two unions boil down to the whole universe U .

The key idea of the rough set approach is explanation (approximation) of knowledge generated by the decision attributes, by *granules of knowledge* generated by condition attributes.

In DRSA, where condition attributes are criteria and decision classes are preference ordered, the knowledge to be explained is the assignment of objects to *upward* and *downward unions of classes* and the granules of knowledge are sets of objects contained in *dominance cones* defined in the space of evaluation criteria.

We say that object x *dominates* object y with respect to $P \subseteq I$ (shortly, x *P-dominates* y), denoted by $x D_P y$, if for every criterion $i \in P$, $g_i(x) \geq g_i(y)$. The relation of *P-dominance* is reflexive and transitive, that is, it is a partial preorder.

Given a set of criteria $P \subseteq I$ and $x \in U$, the granules of knowledge used for approximation in DRSA are:

- a set of objects dominating x , called *P-dominating set*,
 $D_P^+(x) = \{y \in U : y D_P x\}$,
- a set of objects dominated by x , called *P-dominated set*,
 $D_P^-(x) = \{y \in U : x D_P y\}$.

In terms of multiple criteria evaluations, the above definitions correspond to:

$$D_P^+(x) = \{y \in U : g_i(y) \geq g_i(x), \text{ for all } i \in P\},$$

$$D_P^-(x) = \{y \in U : g_i(y) \leq g_i(x), \text{ for all } i \in P\}.$$

Let us recall that the dominance principle requires that an object x dominating object y with respect to considered criteria (i.e., x having evaluations at least as good as y on all considered criteria) should also dominate y on the decision (i.e., x should be assigned to at least as good decision class as y). This principle is the only objective principle that is widely agreed upon in the multiple criteria comparisons of objects.

Given $P \subseteq I$, the inclusion of an object $x \in U$ to the upward union of classes $Cl_t^{\geq}$, $t = 2, \dots, m$, is *inconsistent with the dominance principle* if one of the following conditions holds:

- x belongs to class Cl_t or better but it is *P-dominated* by an object y belonging to a class worse than Cl_t , i.e., $x \in Cl_t^{\geq}$ but $D_P^+(x) \cap Cl_{t-1}^{\leq} \neq \emptyset$,

- x belongs to a worse class than Cl_t but it P -dominates an object y belonging to class Cl_t or better, i.e., $x \notin Cl_t^{\geq}$ but $D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset$.

If, given a set of criteria $P \subseteq I$, the inclusion of $x \in U$ to $Cl_t^{\geq}$, where $t = 2, \dots, m$, is inconsistent with the dominance principle, we say that x belongs to $Cl_t^{\geq}$ *with some ambiguity*. Thus, x belongs to $Cl_t^{\geq}$ *without any ambiguity* with respect to $P \subseteq I$, if $x \in Cl_t^{\geq}$, and there is no inconsistency with the dominance principle. This means that all objects P -dominating x belong to $Cl_t^{\geq}$, i.e., $D_P^+(x) \subseteq Cl_t^{\geq}$.

Furthermore, object x *possibly belongs to* $Cl_t^{\geq}$ with respect to $P \subseteq I$ if one of the following conditions holds:

- according to decision attribute d , x belongs to $Cl_t^{\geq}$,
- according to decision attribute d , x does not belong to $Cl_t^{\geq}$, but it is inconsistent in the sense of the dominance principle with an object y belonging to $Cl_t^{\geq}$.

In terms of ambiguity, x possibly belongs to $Cl_t^{\geq}$ with respect to $P \subseteq I$, if x belongs to $Cl_t^{\geq}$ with or without any ambiguity. Owing to the reflexivity of the dominance relation D_P , the above conditions can be summarized as follows: x *possibly belongs to* class Cl_t or better, with respect to $P \subseteq I$, if among the objects P -dominated by x there is an object y belonging to class Cl_t or better, that is, $D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset$.

The P -lower approximation of $Cl_t^{\geq}$, denoted by $\underline{P}(Cl_t^{\geq})$, and the P -upper approximation of $Cl_t^{\geq}$, denoted by $\overline{P}(Cl_t^{\geq})$, are defined as follows ($t = 2, \dots, m$):

$$\begin{aligned}\underline{P}(Cl_t^{\geq}) &= \{x \in U : D_P^+(x) \subseteq Cl_t^{\geq}\}, \\ \overline{P}(Cl_t^{\geq}) &= \{x \in U : D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset\}.\end{aligned}$$

Analogously, one can define the P -lower approximation and the P -upper approximation of $Cl_t^{\leq}$, as follows ($t = 1, \dots, m-1$):

$$\begin{aligned}\underline{P}(Cl_t^{\leq}) &= \{x \in U : D_P^-(x) \subseteq Cl_t^{\leq}\}, \\ \overline{P}(Cl_t^{\leq}) &= \{x \in U : D_P^+(x) \cap Cl_t^{\leq} \neq \emptyset\}.\end{aligned}$$

The P -boundaries of $Cl_t^{\geq}$ and $Cl_t^{\leq}$, denoted by $Bn_P(Cl_t^{\geq})$ ($t = 2, \dots, m$) and $Bn_P(Cl_t^{\leq})$ ($t = 1, \dots, m-1$), respectively, are defined as follows:

$$\begin{aligned}Bn_P(Cl_t^{\geq}) &= \overline{P}(Cl_t^{\geq}) - \underline{P}(Cl_t^{\geq}), \\ Bn_P(Cl_t^{\leq}) &= \overline{P}(Cl_t^{\leq}) - \underline{P}(Cl_t^{\leq}).\end{aligned}$$

For every $P \subseteq I$, the objects that are consistent in the sense of the dominance principle with all upward and downward unions of classes are P -correctly classified. For every $P \subseteq I$, the *quality of classification* $\mathbf{Cl}$ by a set of criteria $P \subseteq I$ is defined as the ratio of the number of objects P -consistent with the dominance principle and the number of all the objects in U . Since the P -consistent objects are those that do not belong to any P -boundary $Bn_P(Cl_t^{\geq})$ or $Bn_P(Cl_t^{\leq})$, and $Bn_P(Cl_t^{\geq}) = Bn_P(Cl_{t-1}^{\leq})$ for $t = 2, \dots, m$, the quality of classification $\mathbf{Cl}$ by a set of criteria $P \subseteq I$ can be written as

$$\begin{aligned}\gamma_P(\mathbf{Cl}) &= \frac{\left| U - \left(\bigcup_{t \in \{2, \dots, m\}} Bn_P(Cl_t^{\geq}) \right) \right|}{|U|} \\ &= \frac{\left| U - \left(\bigcup_{t \in \{1, \dots, m-1\}} Bn_P(Cl_t^{\leq}) \right) \right|}{|U|}.\end{aligned}$$

$\gamma_P(\mathbf{Cl})$ can be seen as a degree of consistency of the classification examples, where P is the set of criteria and $\mathbf{Cl}$ is the considered classification.

Each minimal (in the sense of inclusion) subset $P \subseteq I$, such that $\gamma_P(\mathbf{Cl}) = \gamma_I(\mathbf{Cl})$, is called a *reduct* of classification $\mathbf{Cl}$ and is denoted by $\text{RED}_{\mathbf{Cl}}$. Let us remark that, for a given set of classification examples, one can have more than one reduct. The intersection of all reducts is called the *core* and is denoted by $\text{CORE}_{\mathbf{Cl}}$. Criteria in $\text{CORE}_{\mathbf{Cl}}$ cannot be removed from consideration without deteriorating the quality of classification $\mathbf{Cl}$. This means that, in set I , there are three categories of criteria:

- *indispensable* criteria included in the core,
- *exchangeable* criteria included in some reducts but not in the core,

- *redundant* criteria, neither indispensable nor exchangeable, and, thus, not included in any reduct.

The dominance-based rough approximations of upward and downward unions of decision classes can serve to induce a generalized description of classification decisions in terms of “if . . . , then . . . ” decision rules. For a given upward or downward union of classes, $Cl_t^{\geq}$ or $Cl_s^{\leq}$, the decision rules induced under a hypothesis that objects belonging to $\underline{P}(Cl_t^{\geq})$ or $\underline{P}(Cl_s^{\leq})$ are positive examples (i.e., objects that have to be matched by the induced decision rules), and all the others are negative (i.e., objects that have to be not matched by the induced decision rules), suggest a *certain* assignment to “class Cl_t or better” or to “class Cl_s or worse”, respectively. On the other hand, the decision rules induced under a hypothesis that objects belonging to $\overline{P}(Cl_t^{\geq})$ or $\overline{P}(Cl_s^{\leq})$ are positive examples, and all the others are negative, suggest a *possible* assignment to “class Cl_t or better”, or to “class Cl_s or worse”, respectively. Finally, the decision rules induced under a hypothesis that objects belonging to the intersection $\overline{P}(Cl_s^{\leq}) \cap \overline{P}(Cl_t^{\geq})$ are positive examples, and all the others are negative, suggest an assignment to some classes between Cl_s and Cl_t ($s < t$). These rules are matching inconsistent objects $x \in U$, which cannot be assigned without doubts to classes Cl_r , $s < r < t$, because $x \notin \underline{P}(Cl_r^{\geq})$ and $x \notin \underline{P}(Cl_r^{\leq})$ for all r such that $s < r < t$.

Given the preference information in terms of classification examples, it is meaningful to consider the following five types of decision rules:

1. *certain* $D_{\geq}$ -decision rules, providing lower profiles (i.e., sets of minimal values for considered criteria) of objects belonging to $\underline{P}(Cl_t^{\geq})$, $P = \{i_1, \dots, i_p\} \subseteq I$: if $g_{i_1}(x) \geq r_{i_1}$ and . . . and $g_{i_p}(x) \geq r_{i_p}$, then $x \in Cl_t^{\geq}$, $t = 2, \dots, m$, $r_{i_1}, \dots, r_{i_p} \in \mathbf{R}$; for example, this is the case of a rule “if maximum speed of car x is at least 175 km/h, and its price (to be minimized) is at most \$ 12,000, then car x is comprehensively at least medium”;
2. *possible* $D_{\geq}$ -decision rules, providing lower profiles of objects belonging to $\overline{P}(Cl_t^{\geq})$, $P = \{i_1, \dots, i_p\} \subseteq I$: if $g_{i_1}(x) \geq r_{i_1}$ and . . . and $g_{i_p}(x) \geq r_{i_p}$, then x possibly belongs to $Cl_t^{\geq}$, $t = 2, \dots, m$, $r_{i_1}, \dots, r_{i_p} \in \mathbf{R}$; for example, this is the case of a rule “if maximum speed of car x is at least 130 km/h, and its fuel consumption (to be minimized) is at most 7 l/100 km, then car x is possibly comprehensively at least medium”;
3. *certain* $D_{\leq}$ -decision rules, providing upper profiles (i.e., sets of maximal values for considered criteria) of objects belonging to $\underline{P}(Cl_t^{\leq})$, $P = \{i_1, \dots, i_p\} \subseteq I$: if $g_{i_1}(x) \leq r_{i_1}$ and . . . and $g_{i_p}(x) \leq r_{i_p}$, then $x \in Cl_t^{\leq}$, $t = 1, \dots, m-1$, $r_{i_1}, \dots, r_{i_p} \in \mathbf{R}$; for example, this is the case of a rule “if maximum speed of car x is at most 140 km/h, and its price is at least \$ 18,000, then car x is comprehensively at most medium”;
4. *possible* $D_{\leq}$ -decision rules, providing upper profiles of objects belonging to $\overline{P}(Cl_t^{\leq})$, $P = \{i_1, \dots, i_p\} \subseteq I$: if $g_{i_1}(x) \leq r_{i_1}$ and . . . and $g_{i_p}(x) \leq r_{i_p}$, then x possibly belongs to $Cl_t^{\leq}$, $t = 1, \dots, m-1$, $r_{i_1}, \dots, r_{i_p} \in \mathbf{R}$; for example, this is the case of a rule “if maximum speed of car x is at most 140 km/h, and its fuel consumption is at least 6 l/100 km, then car x is possibly comprehensively at most medium”;
5. *approximate* $D_{\geq\leq}$ -decision rules, providing simultaneously lower and upper profiles of objects belonging to $Cl_s \cup Cl_{s+1} \cup \dots \cup Cl_t$, without possibility of discerning to which class: if $g_{i_1}(x) \geq r_{i_1}$ and . . . and $g_{i_k}(x) \geq r_{i_k}$ and $g_{i_{k+1}}(x) \leq r_{i_{k+1}}$ and . . . and $g_{i_p}(x) \leq r_{i_p}$, then $x \in Cl_s \cup Cl_{s+1} \cup \dots \cup Cl_t$, $\{i_1, \dots, i_p\} \subseteq I$, $s, t \in \{1, \dots, m\}$, $s < t$, $r_{i_1}, \dots, r_{i_p} \in \mathbf{R}$; for example, this is the case of a rule “if maximum speed of car x is at least 140 km/h, and its fuel consumption is at least 6 l/100 km, then car x is comprehensively medium or good”.

The rules of type 1 and 3 represent certain knowledge extracted from the data table, while the rules of type 2 and 4 represent

possible knowledge. Rules of type 5 represent doubtful knowledge. Algorithms for induction of decision rules from rough approximations of upward and downward unions of decision classes have been described in [22, 23].

It is well known that the computational complexity of the problem of searching for reducts, as well as the problem of generating minimal-cover or all decision rules, is NP-complete, even if the attributes are not ordered (CRSA) [14]. Consideration of ordered attributes (criteria) does not increase the computational complexity [22]. For this reason, for large scale problems, efficient heuristics have been proposed, which perform pretty good. In case of very big data, sampling and bagging techniques are recommended. It is also worth mentioning that there is an advantage in consideration of ordered instead of unordered attributes: in case of ordered attributes, the granules used to build approximations are dominance cones in the evaluation space, with the origins in particular objects; however, in case of unordered attributes, the granules are limited hypercubes in the evaluation space, resulting from discretization of this space. As discretization is always arbitrary to some extent, and it has an impact on the results, it is good to note that DRSA does not require discretization.

More detailed surveys and tutorials on DRSA can be found in [21, 24–26].

An Illustrative Practical Example

Similar to our previous tutorials (e.g., [26–28]), to illustrate the application of DRSA to a real-world multicriteria classification problem, we will use a part of the data provided by a Greek industrial bank ETEVA, which finances industrial and commercial firms in Greece [29]. A sample composed of 39 firms has been chosen for the study in co-operation with the ETEVA's financial manager. The manager has classified the selected firms into three classes of bankruptcy risk. The sorting decision is represented by decision attribute d , making a trichotomic partition of the 39 firms:

$d=A$ means “acceptable”,
 $d=U$ means “uncertain”,
 $d=NA$ means “nonacceptable”.

The partition is denoted by $\mathbf{CI} = \{Cl_A, Cl_U, Cl_{NA}\}$ and, obviously, class Cl_A is better than Cl_U , which is better than Cl_{NA} .

The firms were evaluated using the following 12 criteria ($\uparrow$ means *preference increasing with value* and $\downarrow$ means *preference decreasing with value*):

- g_1 = earnings before interests and taxes/total assets, $\uparrow$
- g_2 = net income/net worth, $\uparrow$
- g_3 = total liabilities/total assets, $\downarrow$
- g_4 = total liabilities/cash flow, $\downarrow$
- g_5 = interest expenses/sales, $\downarrow$
- g_6 = general and administrative expense/sales, $\downarrow$
- g_7 = managers' work experience, $\uparrow$ (very low=1, low=2, medium=3, high=4, very high=5)
- g_8 = firm's market niche/position, $\uparrow$ (bad=1, rather bad=2, medium=3, good=4, very good=5)
- g_9 = technical structure—facilities, $\uparrow$ (bad=1, rather bad=2, medium=3, good=4, very good=5)
- g_{10} = organization—personnel, $\uparrow$ (bad=1, rather bad=2, medium=3, good=4, very good=5)
- g_{11} = special competitive advantage of firms, $\uparrow$ (low=1, medium=2, high=3, very high=4)
- g_{12} = market flexibility, $\uparrow$ (very low=1, low=2, medium=3, high=4, very high=5).

The first six criteria are cardinal (financial ratios) and the last six are ordinal. The data table is presented in Table 1.

The main questions to be answered by the knowledge discovery process were the following:

- Is the information contained in Table 1 consistent?
- What are the reducts of criteria ensuring the same quality of approximation

Table 1. Financial Data Matrix

Firm	g_1	g_2	g_3	g_4	g_5	g_6	g_7	g_8	g_9	g_{10}	g_{11}	g_{12}	d (class)
F1	16.4	14.5	59.82	2.5	7.5	5.2	5	3	5	4	2	4	A

of the multicriteria classification as the whole set of criteria?

- What decision rules can be extracted from Table 1?
- What are the minimal sets of decision rules?

We will answer these questions using DRSA. The **first result** from this approach is a discovery that the financial data matrix

is **consistent** for the complete set of criteria C . Therefore, the C -lower and C -upper approximations of $Cl_{NA}^{\leq}, Cl_U^{\leq}$ and $Cl_U^{\geq}, Cl_A^{\geq}$ are, respectively, the same. In other words, the quality of approximation of all upward and downward unions of classes, as well as the quality of classification, is equal to 1.

The **second discovery** is a set of 18 **reducts** of criteria ensuring the same quality of classification as the whole set of 12 criteria:

$$\begin{aligned}
\text{RED}_{\text{CI}}^1 &= \{g_1, g_4, g_5, g_7\}, & \text{RED}_{\text{CI}}^2 &= \{g_2, g_4, g_5, g_7\}, \\
\text{RED}_{\text{CI}}^3 &= \{g_3, g_4, g_6, g_7\}, & \text{RED}_{\text{CI}}^4 &= \{g_4, g_5, g_6, g_7\}, \\
\text{RED}_{\text{CI}}^5 &= \{g_4, g_5, g_7, g_8\}, & \text{RED}_{\text{CI}}^6 &= \{g_2, g_3, g_7, g_9\}, \\
\text{RED}_{\text{CI}}^7 &= \{g_1, g_3, g_4, g_7, g_9\}, & \text{RED}_{\text{CI}}^8 &= \{g_1, g_5, g_7, g_9\}, \\
\text{RED}_{\text{CI}}^9 &= \{g_2, g_5, g_7, g_9\}, & \text{RED}_{\text{CI}}^{10} &= \{g_4, g_5, g_7, g_9\}, \\
\text{RED}_{\text{CI}}^{11} &= \{g_5, g_6, g_7, g_9\}, & \text{RED}_{\text{CI}}^{12} &= \{g_4, g_5, g_7, g_{10}\}, \\
\text{RED}_{\text{CI}}^{13} &= \{g_1, g_3, g_4, g_7, g_{11}\}, & \text{RED}_{\text{CI}}^{14} &= \{g_2, g_3, g_4, g_7, g_{11}\}, \\
\text{RED}_{\text{CI}}^{15} &= \{g_4, g_5, g_6, g_{12}\}, & \text{RED}_{\text{CI}}^{16} &= \{g_1, g_3, g_5, g_6, g_9, g_{12}\}, \\
\text{RED}_{\text{CI}}^{17} &= \{g_3, g_4, g_6, g_{11}, g_{12}\}, & \text{RED}_{\text{CI}}^{18} &= \{g_1, g_2, g_3, g_6, g_9, g_{11}, g_{12}\}.
\end{aligned}$$

All the eighteen subsets of criteria are equally good and sufficient for the perfect approximation of the classification performed by ETEVA's financial manager on the 39 firms. The core of CI is empty ($\text{CORE}_{\text{CI}} = \emptyset$), which means that no criterion is indispensable for the approximation. Moreover, all the criteria are exchangeable, and no criterion is redundant.

The **third discovery** is the set of *all* decision rules. We obtained 74 rules describing $\text{Cl}_{\text{NA}}^{\leq}$, 51 rules describing $\text{Cl}_{\text{U}}^{\leq}$, 75 rules describing $\text{Cl}_{\text{U}}^{\geq}$, and 79 rules describing $\text{Cl}_{\text{A}}^{\geq}$.

The **fourth discovery** is the finding of *minimal sets* of decision rules. Several minimal sets were found. One of them is shown below. The number in parenthesis indicates the number of objects (firms) that support the corresponding rule, that is, the rule strength:

1. **if** $g_3(x) \geq 67.5$ **and** $g_4(x) \geq -2.2$ **and** $g_6(x) \geq 8.7$, **then** $x \in \text{Cl}_{\text{NA}}^{\leq}$, (4),
2. **if** $g_2(x) \leq 3.3$ **and** $g_7(x) \leq 2$, **then** $x \in \text{Cl}_{\text{NA}}^{\leq}$, (5),
3. **if** $g_3(x) \geq 63.6$ **and** $g_7(x) \leq 3$ **and** $g_9(x) \leq 3$, **then** $x \in \text{Cl}_{\text{NA}}^{\leq}$, (4),
4. **if** $g_2(x) \leq 12.4$ **and** $g_6(x) \geq 5.6$, **then** $x \in \text{Cl}_{\text{U}}^{\leq}$, (14),
5. **if** $g_7(x) \leq 3$, **then** $x \in \text{Cl}_{\text{U}}^{\leq}$, (18),
6. **if** $g_2(x) \geq 3.5$ **and** $g_5(x) \leq 8.5$, **then** $x \in \text{Cl}_{\text{U}}^{\geq}$, (26),
7. **if** $g_7(x) \geq 4$, **then** $x \in \text{Cl}_{\text{U}}^{\geq}$, (21),
8. **if** $g_1(x) \geq 8.7$ **and** $g_9(x) \geq 4$, **then** $x \in \text{Cl}_{\text{U}}^{\geq}$, (27),
9. **if** $g_2(x) \geq 3.5$ **and** $g_7(x) \geq 4$, **then** $x \in \text{Cl}_{\text{A}}^{\geq}$, (20).

As the minimal set of rules is complete and composed of $\text{D}_{\geq}$ -decision rules and $\text{D}_{\leq}$ -decision rules only, application of these rules to the 39 firms will result in their exact reclassification to classes of risk.

Minimal sets of decision rules represent the most concise and nonredundant knowledge representations. The above minimal set of 9 decision rules uses 8 criteria and 18 elementary conditions, that is, 3.85% of descriptors from the financial data matrix.

DRSA FOR MULTIPLE-CRITERIA CHOICE AND RANKING

DRSA can also be applied to multiple criteria choice and ranking problems. However, there is a basic difference between classification problems from one side, and choice and ranking from the other side. To give a didactic example, consider a set of companies A for evaluation of a risk of failure, taking into account the debt ratio criterion. To assess the risk of failure of company x , we will not compare the debt ratio of x with the debt ratio of all the other companies from A . The comparison will be made with respect to a fixed risk threshold on the debt ratio criterion. Indeed, the debt ratio of x can be the highest of all companies from A , and nevertheless, x can be classified as a low risk company if its debt ratio is below the fixed risk threshold. Consider, in turn, the situation, in which we must choose the lowest risk company from A or we want to rank these companies from the less risky to the most risky one. In this situation, the comparison of the debt ratio of x with a

fixed risk threshold is not useful, and instead, a pairwise comparison of the debt ratio of x with the debt ratio of all other companies in A is relevant for the choice or ranking. Thus, in general, while classification is based on absolute evaluation of objects (e.g., comparison of the debt ratio with the fixed risk threshold), choice and ranking refer to relative evaluation, by means of pairwise comparisons of objects (e.g., comparisons of the debt ratios for pairs of companies).

The necessity of pairwise comparisons of objects in multiple criteria choice and ranking problems requires some further extensions of DRSA. Simply speaking, in this context, we are interested in the approximation of a binary relation (corresponding to a comprehensive preference relation) using other binary relations (corresponding to marginal preference relations on particular criteria) for pairs of objects. In the above example, we would approximate the binary relation “from the viewpoint of the risk of failure, company x is comprehensively preferred to company y ”, using binary relations on the debt ratio criterion, like “the debt ratio of x is *much better* than that of y ” or “the debt ratio of x is *weakly better* than that of y ”, and so on.

Technically, the modifications of DRSA necessary to approach the problems of choice and ranking are twofold:

1. *Pairwise comparison table* (PCT) is considered instead of the simple data table [19]: PCT is a data table whose rows represent pairs of objects for which multiple criteria evaluations and a comprehensive preference relation are known;
2. *dominance principle* is considered for comparisons of pairs of objects instead of simple objects: if object x is preferred to y at least as strongly as w is preferred to z on all the considered criteria, then x must be comprehensively preferred to y at least as strongly as w is comprehensively preferred to z .

The application of DRSA to the choice or ranking problems proceeds as follows. First, the DM gives examples of comparison of pairs

of some reference objects, well known to the DM. This can be a complete ranking from the best to the worst of a limited number of such objects. From this set of examples, a preference model in terms of “*if . . . , then . . .*” decision rules is induced. These rules are applied to a larger set of objects. In result, one gets a preference relation in this set of objects. A proper exploitation of this preference relation leads to a final recommendation for the decision problem at hand. For more details about application of DRSA to the choice and ranking problems, see [30].

OTHER DEVELOPMENTS FOR DRSA

Other interesting fields of research and applications involving DRSA are discussed further.

DRSA with a Joint Consideration of Dominance, Indiscernibility, and Similarity Relations

Very often, in data tables describing realistic decision problems, there are data referring to a preference order (criteria), for which a dominance relation has to be considered, together with data not referring to any specific preference order (attributes). The latter can be data referring to nominal (symbolic) description, for which an indiscernibility relation has to be considered, and data referring to quantitative (numeric) description, for which a similarity relation has to be considered in the set of objects. Let us remark that indiscernibility is the binary relation considered within the CRSA, while an extension of rough sets to the similarity relation has been proposed by Słowiński and Vanderpooten [31, 32] (for a fuzzy extension of this approach see [33, 34]). Greco *et al.* [20, 35] proposed an extension of DRSA to deal with data table where preference, indiscernibility, and similarity are to be considered jointly.

DRSA and Interval Orders

Owing to imprecise measurement, random variation of some parameters, unstable perception, or incomplete definition of both evaluation scales of criteria and decision classes, some evaluations on particular

criteria and/or some assignments to decision classes considered in a data table may not be univocal. DRSA adapted to this situation has been proposed in [36]. Its basic idea consists in approximation of an interval order of the comprehensive evaluation by means of interval orders on particular criteria; the key concept of this approximation is a specially defined dominance relation.

Fuzzy DRSA—Rough Approximations by Means of Fuzzy Dominance Relations

The concept of dominance can be refined by introducing gradedness through the use of fuzzy sets in the sense of semantics expressing preferences for pairs of objects (for a detailed presentation of fuzzy preferences see [37]). The gradedness introduced by the use of fuzzy sets refines the classic crisp preference structures. Such a reasoning about a smooth transition from truth to falsity of an inclusion relation can be applied to the dominance relation considered in the rough approximations. In [18,38,39] and in [40], DRSA was extended by using fuzzy dominance relation in two different ways. These extensions of the rough approximation into the fuzzy context maintain the same desirable properties of the crisp rough approximation of preference-ordered decision classes. They follow the traditional way of using fuzzy logical connectives in definitions of lower and upper approximations. In fact, however, there is no rule for the choice of the “right” connective; so, this choice is always arbitrary to a certain extent. For this reason, in [41–43], a new fuzzy rough approximation was proposed. It avoids the use of fuzzy connectives, such as T -norm, T -conorm, and fuzzy implication, which extend “and”, “or”, and “if . . . , then . . .” operators within fuzzy logic (see, e.g., [37]), at the price of introducing a certain degree of subjectivity related to the choice of one or another of their functional forms. The proposed approach solves this problem because it is based on the ordinal properties of fuzzy membership functions only. It employs DRSA to cope in a natural way with the monotonic relationship between grades of membership to the concepts (evaluations and classes) on condition and decision sides of objects’ description.

DRSA with Missing Values—Multiple Criteria Classification Problem with Missing Values

In practical applications, the data table is often incomplete because some data are missing. An extension of DRSA enabling the analysis of incomplete data tables has been proposed in [44] and [45]. In this extension, it is assumed that the dominance relation between two objects is a directional statement, where a subject object is compared to a referent object having no missing values on considered criteria. The advantage of this approach is that the rules induced from the rough approximations defined using the extended dominance relation are *robust*, that is, each rule is supported by at least one object with no missing value on the criteria represented in the condition part of the rule. To better understand this feature, let us mention that, in another approach proposed to deal with missing values [46, 47], an object having a missing value is replaced by a set of objects obtained by putting each possible evaluation in the place of the missing value.

DRSA extended to deal with missing values maintains all good characteristics of the dominance-based rough set approach and boils down to the latter when there are no missing values. This approach can also be used to analyze a data table in which dominance, similarity, and indiscernibility must be considered jointly with respect to criteria and attributes.

DRSA for Hierarchical Structure of Attributes and Criteria

In many real life situations, the process of decision-making can be decomposed into sub-problems; this decomposition may either follow from a natural hierarchical structure of the evaluation or from a need of simplification of a complex decision problem. These situations are referred to hierarchical decision problems. The structure of a hierarchical decision problem has the form of a tree whose nodes are attributes and criteria describing the objects. In [48], hierarchical decision problems are considered where the decision is made in a finite number of steps because of a hierarchical structure

of regular attributes and criteria. The proposed methodology is based on decision rule preference model induced from examples of hierarchical decisions made by the DM on a set of reference objects. To deal with inconsistencies appearing in decision examples, DRSA has been adapted to hierarchical classification problems. In these problems, the main difficulty consists in propagation of inconsistencies along the tree, that is, taking into account at each node of the tree the inconsistent information coming from lower level nodes. In the proposed methodology, the inconsistencies are propagated from the bottom to the top of the tree in the form of subsets of possible attribute values instead of single values. In the case of hierarchical criteria, these subsets are intervals of possible criterion values. Subsets of possible values may also appear in leafs of the tree, that is, in evaluations of objects by the lowest level attributes and criteria. To deal with multiple values of attributes in description of objects, the CRSA has been adapted adequately. Interval evaluations of objects on particular criteria can be handled by DRSA extended to interval orders [48].

DRSA AND OPERATIONS RESEARCH PROBLEMS

DRSA is also a useful instrument in the toolbox of operations research (OR). DRSA has been applied to the following OR problems:

1. interactive multiobjective optimization (IMO-DRSA) [11];
2. interactive evolutionary multiobjective optimization under risk and uncertainty [49];
3. decision under uncertainty and time preference [50].

DRSA to Interactive Multiobjective Optimization (IMO-DRSA)

IMO-DRSA [11] permits to deal with many optimization problems considered within OR (ranging from inventory management to scheduling, passing through portfolio management) in a way that is very much oriented toward interaction with the users. In fact,

in IMO-DRSA, a sample of representative solutions to a multiobjective optimization problem is presented to the DM who is asked to indicate a subset of relatively “good” solutions in the sample. Applying DRSA to the sample of representative solutions classified into “good” and “others” by the DM, a set of decision rules is induced in the form: “if objective $f_{i_1}(x) \geq \alpha_{i_1}$ and ... objective $f_{i_p}(x) \geq \alpha_{i_p}$, then x is a *good* solution”. The DM selects the rule that in his/her opinion is the most representative of his/her preferences, and the constraints coming from that rule are joined to the set of constraints imposed on the Pareto optimal set, in order to focus on a part interesting from the point of view of DM’s preferences in the next iteration. For example, if the DM selects the rule “if objective $f_{i_1}(x) \geq \alpha_{i_1}$ and ... objective $f_{i_p}(x) \geq \alpha_{i_p}$, then x is a *good* solution”, then the constraints $f_{i_1}(x) \geq \alpha_{i_1}$ and ... $f_{i_p}(x) \geq \alpha_{i_p}$ are joined to the set of constraints of the multiobjective optimization problem, such that the new set of constraints implies a Pareto optimal set being the subset of the original Pareto optimal set. This subset satisfies the requirements of the selected rule, so that it is composed of solutions that are at this stage considered as relatively good by the DM. The procedure continues iteratively until the DM is satisfied with one solution from the current sample—this is the most preferred solution.

DRSA to Interactive Evolutionary Multiobjective Optimization (EMO-DRSA)

Very often, real life optimization problems are so complex that exact methods fail to find an optimal solution. In these cases, some heuristics are to be applied. Within multiobjective optimization, EMO appeared to be particularly efficient; see, for example, [51, 52]. The underlying reasoning behind the EMO search of an approximation of the Pareto optimal frontier is that, in the absence of any preference information, all Pareto optimal solutions have to be considered equivalent. On the other hand, if the DM (alternatively called *user*) is involved in the multiobjective optimization process, then the preference information provided

by the DM can be used to focus the search on the most preferred part of the Pareto optimal frontier. This idea stands behind IMO methods proposed long time before EMO has emerged. Recently, it became clear that merging the IMO and EMO methodologies should be beneficial for the multiobjective optimization process [53]. Several approaches have been presented in this context; see, for example, [51, 54–61]. The methodology of interactive EMO based on DRSA [49, 62], involves application of decision rules in EMO, which are induced from easily elicited preference information by DRSA, proposing two general schemes, called *DRSA-EMO* and *DRSA-EMO-PCT*. This results in focusing the search of the Pareto optimal frontier on the most preferred region. More specifically, DRSA is used for structuring preference information obtained through interaction with the user, and then, a set of decision rules representing user's preferences is induced from this information. These rules are used to rank solutions in the current population of EMO, which has an impact on the selection and crossover. Within interactive EMO, one can also apply DRSA for decision under uncertainty. This permits to take into account robustness concerns in the multiobjective optimization. In fact, two methods of robust optimization methods combining DRSA and interactive EMO have been proposed: DARWIN [49] (dominance-based rough set approach to handling robust winning solutions in interactive multiobjective optimization) and DARWIN-PCT [62] (DARWIN using pairwise comparison tables). DARWIN and DARWIN-PCT can be considered as two specific instances of *DRSA-EMO* and *DRSA-EMO-PCT*, respectively.

DRSA to Decision Under Uncertainty and Time Preference

DRSA can also be applied to preference modeling for decision under uncertainty with consequences distributed over time, using the idea of time-stochastic dominance, that is, putting together the concept of time dominance and stochastic dominance [50]. Preference information provided by the DM is a set of decision examples specifying the quality of

some chosen acts, that is, assigning these acts to preference-ordered classes. The resulting preference model expressed in terms of “*if... then...*” decision rules is much more intelligible than any utility function. Moreover, it permits to handle inconsistent preference information. Let us observe that the approach handles additive and nonadditive probability distribution and even a qualitative ordinal probability. Furthermore, in case, the elements of sets of possible probability values and of time epochs were very numerous (like in real life applications in which very often they are infinite), it would be enough to consider a subset of the most significant probability values (e.g., 0, 0.1, 0.2, ..., 0.9, 1) and a subset of the most significant epochs (e.g., each month). Applying DRSA to decision under uncertainty and time preference, we get decision rules of the type:

“if the cumulated outcome at t_1 is at least 50 with a probability of 0.5, and the cumulated outcome at t_2 is at least 300 with a probability of 0.7, then act a is (at least) good”,

or

“if the cumulated outcome at t_1 is at most 100 with a probability of 0.25, and the cumulated outcome at t_2 is at most 150 with a probability of 0.8, then act a is at most medium”.

This method can be extended on the case of pairwise comparisons [63], obtaining rules whose syntax is:

“if the difference between the cumulated outcome of act a and act b is not smaller than 50 at t_1 with a probability of 0.6 and not smaller than 300 at t_2 with a probability of 0.4, then act a is at least weakly preferred to act b ”.

The above methodology can be very useful for dealing with many OR problems where uncertainty of outcomes and their distribution over the time play a fundamental role, such as portfolio selection, scheduling with time–resource interactions, and inventory management. Indeed, putting the decision rules produced by this methodology together with IMO-DRSA and DRSA applied to EMO provides an important tool for dealing with even more OR problems. Examples of recent applications of this methodology to typical OR problems, which are inventory

control and portfolio selection, can be found in [64] and [65], respectively.

DECISION-THEORETIC FOUNDATIONS OF SIMULATION OPTIMIZATION

PETER I. FRAZIER
School of Operations Research
and Information Engineering,
Cornell University, Ithaca,
New York

Simulation is an invaluable tool in operations research (OR) and management science (MS). We may use it whenever we wish to manipulate a system to see what would happen, but actually performing the manipulation in reality would be too expensive, too risky, or simply impossible. Instead of manipulating the real system, we can build a simulation of the system and manipulate that instead.

In OR and MS, we often focus on stochastic simulation, and, in particular, on stochastic discrete-event simulation [1]. Important examples of systems simulated in this way include supply chains, queueing systems, manufacturing systems, and financial markets. The mathematical techniques that we will describe here may also be applied to simulations of systems of interest in engineering, medicine, and the natural sciences, for example, simulations of the physical and chemical processes in a combustion engine.

Often, our goal in building a simulation is to optimize the real system. To do so, we may test a variety of possible actions using the simulation, find the one that performs best in simulation, and implement it in the real system. For example, we may simulate inventory policies in a supply chain to minimize expected costs, or we may simulate methods for repositioning ambulances in a city to maximize the number of calls answered in a timely manner. Finding the inputs to a simulation that maximize some aspect of its output is called *simulation optimization*.

A related goal is *calibration* of a simulated system. In calibration, we search for parameter settings that cause the simulation to behave as similarly as possible to the real

system. For example, we may search for a parametric model of credit risk in a financial market that causes predicted prices of liquidly traded securities to match market prices, or we may search for a representation of consumer behavior that cause simulated sales data to match what is observed in practice. Because we are searching for simulation inputs that cause its output to match a target as well as possible, calibration is also a simulation optimization problem.

In general, any simulation optimization problem may be written as

$$\max_{x \in \mathcal{X}} \mathbb{E}[f(x, W)], \quad (1)$$

where f is a function implemented by the logic of the simulation (often highly complicated), W is random variable (often highly multivariate) generated by the random number generator inside the simulation, and $\mathcal{X}$ is the set of possible inputs to the simulation. In this article, we will consider two cases. In the first case, called *ranking and selection* (R&S), $\mathcal{X}$ a finite set. In the second case, called *Bayesian Global Optimization* (BGO) $\mathcal{X}$ is a subset of $\mathbb{R}^d$ and $x \mapsto \mathbb{E}[f(x, W)]$ is a continuous function.

Simulation optimization differs from other types of optimization in that it does not rely on an analytic expression for $\mathbb{E}[f(x, W)]$. This makes simulation optimization more flexible than other types of optimization, but also more challenging. In most simulations, f is very complicated, and W is highly multivariate, and so an analytic expression is simply not available. Instead, the only way to estimate $\mathbb{E}[f(x, W)]$ is to run the simulator many times with the same input x , but different randomly generated values of W , say $W_1, \dots, W_n$, and average the outputs $f(x, W_1), \dots, f(x, W_n)$. Accurately estimating $\mathbb{E}[f(x, W)]$ for even a single value of x may require many simulations and a great deal of computer time.

The goal of the field of simulation optimization is to design algorithms that will solve Equation (1) as quickly and accurately

as possible. Simulations of highly complex systems often require significant amounts of time to generate samples of $f(x, W)$, and so an algorithm that solves the problem with fewer samples can save a significant amount of time. In situations with large search spaces $\mathcal{X}$ or very time-consuming simulation, an efficient algorithm may make a solution to Equation (1) available, where otherwise a solution would be impossible to find. For example, if a large discrete-event simulation takes 30 min of computer time to generate a single sample, then an algorithm that solves the problem to reasonable accuracy with 100 samples could be used in practice, while an algorithm that requires 10^6 samples would not (the first requires 50 h of computer time, while the second requires more than 50 years).

At its heart, an algorithm is a sequence of decisions—decisions about which points x to sample with the simulation (the “allocation or measurement decisions”), a decision of when to stop sampling (the “stopping decision”), and at the end, a decision of which point x^* to declare as an approximate solution (the “selection decision”). Thus, decision theory provides a framework in which to assess and compare the quality of different algorithms, and ultimately to guide us toward an optimal algorithm. In particular, since simulation optimization is concerned with the collection of information, it may be understood as a problem in the value of information [2,3].

A number of reviews have been written that consider decision theory applied to the decisions made in simulation, and many of these consider simulation optimization. Many of these reviews [4,5], introduce decision theory to readers already familiar with simulation, while Merrick [6] introduces problems in simulation to readers already familiar with decision theory. Also, we do not consider here the larger field of simulation optimization separated from its decision-theoretic aspects. For such broader discussion, see Refs 7–10.

In this article, we begin by describing the R&S problem in a Bayesian context. This problem is canonical, being simple enough to allow a thorough analysis, while at the same time exemplifying the issues at the

core of all simulation optimization problems. We then discuss a worst-case analysis of R&S called the *indifference-zone formulation*, which is historically more prominent than the Bayesian formulation. We conclude by discussing the BGO problem, in which we optimize a continuous function over a continuous domain and must deal with an infinite number of alternatives.

BAYESIAN RANKING AND SELECTION

The decision-theoretic understanding of simulation optimization is best introduced in the context of the R&S problem. In this problem, a collection of distinct “alternatives,” numbered 1 through k , comprises our set $\mathcal{X}$ of possible inputs to the simulation. We might think of the alternatives as possible configurations of a manufacturing process, or as inventory policies that might be used in a supply chain.

Associated with each alternative x is a sampling distribution, which is the distribution of $f(x, W)$. In R&S, our goal is to maximize $\mathbb{E}[f(x, W)]$, that is, to find the alternative whose sampling distribution has the largest mean. We often assume that the sampling distributions are normal, which is justified by supposing that, when samples are not normal, we average many together to obtain approximately normal batch averages. When the sampling distribution is normal, it is completely determined by its mean and variance. Let θ_x and λ_x be the mean and variance, respectively, of the sampling distribution for alternative x . Let $\theta = (\theta_1, \dots, \theta_k)$ and $\lambda = (\lambda_1, \dots, \lambda_k)$. These values are unknown *a priori*, and simulation is the tool through which we may learn about them.

Whenever we choose to simulate an alternative x , we observe a sample from this sampling distribution. In R&S, we often assume that samples are independent over time and across the alternatives. Let n index the number of samples observed, and let x_n be the alternative that is observed at time n . We may choose x_n based on previous samples, and it is this choice or decision, along with the stopping decision, that is the main focus within R&S. For each $n \geq 1$ we observe a

value y_n that results from sampling alternative x_n . It has a distribution

$$y_n \sim \text{Normal}(\theta_{x_n}, \lambda_{x_n}) \mid x_n, \theta, \lambda,$$

and is independent of all previous allocation decisions and samples, that is, of x_m and y_m , $m < n$.

By taking more samples, we learn more about the sampling distributions and we improve our ability to find the best one. However, taking more samples consumes more time. In some formulations of the R&S problem, the amount of time that we may spend sampling is constrained. In others, we control how much time we spend sampling, but sampling incurs an explicit cost that we must balance against the value of the information obtained. In this section we will suppose an explicit cost $c > 0$ for each sample taken.

Let τ be the number of samples taken. As with the decision of which alternatives to sample, the decision to stop taking samples may be made adaptively, based on the samples observed so far. After we stop sampling, we select an alternative for implementation based on the accumulated evidence. Call the alternative selected x^* . Our selection decision may depend on $x_1, \dots, x_\tau$ and $y_1, \dots, y_\tau$. As stated, we wish to select the alternative with the largest sampling mean, $\arg \max_x \theta_x$. When we make a mistake and we fail to select the one with the largest θ_x , we suffer a loss $L(x^*, \theta)$, where L is our loss function. Common loss functions are the linear loss function $L(x^*, \theta) = \max_x \theta_x - \theta_{x^*}$, and the 0–1 loss function $L(x^*, \theta) = \mathbf{1}_{\{x^* \neq \arg \max_x \theta_x\}}$. One could also consider a loss function depending on both θ and λ , although commonly this is not considered. In addition to this loss associated with an incorrect selection, we also pay the cost of sampling, which is $c\tau$. Thus, the total loss is $L(x^*, \theta) + c\tau$.

Let π be a generic set of rules for making the decisions τ , $(x_n)_{n \leq \tau}$, and x^* . We call this set of rules a *policy*. It must obey the previously stated rules governing the information upon which decisions may be based. These rules require that the decision $\mathbf{1}_{\{\tau=n\}}$ to stop and the decision x_{n+1} of which alternative to sample next (when not stopping) depend only upon $x_{1:n} = (x_1, \dots, x_n)$ and $y_{1:n} = (y_1, \dots, y_n)$.

They also require that the selection decision x^* depend only upon $x_{1:\tau}$ and $y_{1:\tau}$. Given a policy π obeying these rules, and fixed values θ and λ , the expected total loss suffered is

$$R^\pi(\theta, \lambda) = \mathbb{E}^\pi [L(x^*, \theta) + c\tau \mid \theta, \lambda],$$

where $\mathbb{E}^\pi$ indicates that when the expectation is taken, the values τ , $(x_n)_{n \leq \tau}$, and x^* are chosen according to the policy π .

If we knew the true θ and λ , then we would prefer the policy π with the smallest value of $R^\pi(\theta, \lambda)$. However, we do not know these values at all. If we did, we could simply choose $x^* \in \arg \max_x \theta_x$ directly without sampling at all, and achieve 0 loss every time. Since we do not know θ and λ , we instead need a method for combining performance across multiple values of θ and λ to establish a preference order over policies.

In the Bayesian formulation, we place a prior probability distribution on the unknown quantities, θ and λ . In some cases, this is justified because the simulation optimization problem at hand really is drawn at random from some larger set of simulation optimization problems with which we have a great deal of experience and whose distribution we can characterize. One such case might be the calibration of a financial model of credit risk based on current market prices for liquidly traded credit derivatives. The model must be calibrated each day to a new set of market prices, and because the calibration is performed repeatedly, we may estimate the overall distribution of truths θ and λ in the simulation optimization problems encountered, and use this as our prior. Much more frequently, however, the prior probability distribution encodes our subjective belief about θ and λ . This is in keeping with Bayesian methods as used throughout decision theory [11]. If one has very little information concerning θ and λ , it is also possible to specify a noninformative prior distribution.

Given a prior distribution, the Bayes risk (expected total loss under the prior) of a policy π is

$$\mathbb{E} [R^\pi(\theta, \lambda)] = \mathbb{E}^\pi [L(x^*, \theta) + c\tau],$$

where the first expectation is over the truth θ , λ as drawn from the prior, and the second expectation is over both θ , λ , and the intrinsic randomness introduced by the sampling noise. This first expectation lacks a π in the superscript because it is taken only over the prior on θ , λ , which does not depend upon the policy (however, note that $R^\pi(\theta, \lambda)$ does depend on π), while the second expectation has a π in the superscript because the distribution of x^* and τ depends upon the policy.

If a noninformative prior distribution is specified, then the expectation $\mathbb{E}^\pi [L(x^*, \theta) + c\tau]$ may not exist. In such situations, one may perform a first stage of measurements in which each alternative is measured an equal number of times to produce a proper posterior belief. One may then take this resulting belief and use it as the prior under which we formulate the decision-theoretic problem.

Given this prior, whether it is the original prior or the belief resulting from an earlier noninformative prior and a first stage of measurements, we value a policy according to its Bayes risk. One policy is better than the other if it has smaller Bayes risk, and an optimal policy π is one that attains minimal Bayes risk

$$\inf_{\pi \in \Pi} \mathbb{E}^\pi [L(x^*, \theta) + c\tau]. \quad (2)$$

Here, Π is the set of policies considered, and may be the set of all policies, or may be a strict subset, for example, the set of two-stage policies described in the section titled “Allocation and Stopping Rules.” Finding a policy π that attains this infimum is one of the ultimate goals in Bayesian R&S.

Beginning with a prior probability distribution, sampling results in a posterior distribution that combines the prior with evidence from sampling. This posterior may be calculated using Bayes’ rule. Given a set of samples and the resulting posterior distribution, the conditional expected loss of a given selection decision x^* at time τ is

$$\mathbb{E} [L(x^*, \theta) | x_{1:\tau}, y_{1:\tau}].$$

One can show that the best implementation decision x^* is any from the set $\arg \min_x \mathbb{E} [L(x, \theta) | x_{1:\tau}, y_{1:\tau}]$. For the linear loss function, this is the one with the largest posterior mean, but for other loss functions, including the 0–1 loss function, this is not necessarily true [12]. Nevertheless, given a posterior distribution obtained by a given policy, choosing x^* is relatively straightforward.

If we fix the rule for choosing x^* to the optimal method, we may rewrite Equation (2) as

$$\inf_{\pi \in \Pi} \mathbb{E}^\pi \left[\min_{x^*} \mathbb{E} [L(x^*, \theta) | x_{1:\tau}, y_{1:\tau}] + c\tau \right]. \quad (3)$$

Within this expression, $\min_{x^*} \mathbb{E} [L(x^*, \theta) | x_{1:\tau}, y_{1:\tau}]$ is the best that we can do given the information we have collected by time τ , $c\tau$ is the cost we pay for this information, and $\mathbb{E}^\pi [\min_{x^*} \mathbb{E} [L(x^*, \theta) | x_{1:\tau}, y_{1:\tau}] + c\tau]$ is the overall expected net loss incurred by sampling according to the policy π . By subtracting this from the value of taking no samples at all, one obtains $\min_{x'} \mathbb{E} [L(x', \theta)] - \mathbb{E}^\pi [\min_{x^*} \mathbb{E} [L(x^*, \theta) | x_{1:\tau}, y_{1:\tau}] + c\tau]$, which is the net value of the information collected by π .

The challenge in designing algorithms for Bayesian R&S is choosing rules for making allocation and stopping decisions whose expected loss is as close to this minimal value (Eq. 3) as possible. In theory, such rules may be found using dynamic programming (see Refs 13 and 14 for dynamic-programming formulations of R&S), but the amount of computational power that is actually required to find them far exceeds what is currently available. Instead, a number of heuristic rules have been suggested in the literature. We discuss these after introducing the most commonly used prior distributions.

Choice of Prior Probability Distribution

Bayesian R&S is most convenient if the prior resides within a conjugate family for the sampling distribution. The most commonly considered case is

$$\begin{aligned} \theta_x | \lambda_x &\sim \text{Normal}(\mu_{0x}, \lambda_x/t_{0x}), \\ \lambda_x^{-1} &\sim \text{Gamma}(a_{0x}, b_{0x}), \end{aligned}$$

which is parameterized by μ_{0x} , t_{0x} , a_{0x} , b_{0x} , $x = 1, \dots, k$. With this prior and a sequence of samples, the posterior is

$$\begin{aligned}\theta_x \mid \lambda_x, x_{1:n}, y_{1:n} &\sim \text{Normal}(\mu_{nx}, \lambda_x/t_{nx}), \\ \lambda_x^{-1} \mid x_{1:n}, y_{1:n} &\sim \text{Gamma}(a_{nx}, b_{nx}),\end{aligned}$$

where the parameters for the unmeasured alternatives remain unchanged from n to $n + 1$, and the parameters for the measured alternative, $x = x_{n+1}$, can be calculated recursively as

$$\begin{aligned}\mu_{n+1,x} &= (t_{nx}\mu_{nx} + y_{n+1}) / (t_{nx} + 1), \\ t_{n+1,x} &= t_{nx} + 1, \\ b_{n+1,x} &= (y_{n+1} - \mu_{nx})^2 t_{nx} / (2t_{nx} + 2), \\ a_{n+1,x} &= a_{nx} + \frac{1}{2}.\end{aligned}$$

Details, derivations, and the limiting non-informative case may be found in Ref. 15, Sections 9.6 and 10.2.

If λ is known, then the prior-posterior analysis simplifies. The priors and posteriors, for $n \geq 0$, are $\theta_x \sim \text{Normal}(\mu_{nx}, \lambda_x/t_{nx})$, and the parameters of the posterior are updated recursively for $x = x_{n+1}$ as $\mu_{n+1,x} = (t_{nx}\mu_{nx} + y_{n+1}) / (t_{nx} + 1)$, and $t_{n+1,x} = t_{nx} + 1$.

In both cases, as we continue to sample an alternative x , our posterior belief about its sampling mean concentrates around its true sampling mean θ_x . The mean of our belief, μ_{nx} , converges to θ_x , and the variance of our belief shrinks to 0.

Allocation and Stopping Rules

In the framework discussed so far, the decisions made at time $n + 1$ (the measurement decisions x_{n+1} and the decision of whether to stop or not, that is, whether to set $\tau = n + 1$) may be made based upon *all* of the information $x_{1:n}, y_{1:n}$ available.

In some situations, it may be useful to restrict the set of information upon which a decision may be based. This is done for two reasons. The first is to run simulations in parallel—if we have multiple processors, we would like to start several simulations at once without waiting for the results of the

last simulation to decide which alternative to simulate next. The second reason is simplicity of analysis. Complex adaptive policies are usually more difficult to analyze and develop than those with more restrictive information dependencies.

Policies are classified according to the complexity of their information dependence. The simplest policies are those in which the alternatives to sample, $x_{1:\tau}$ are chosen up front. In this case, the x_n and τ are deterministic quantities. These are called *one-shot*, *single-stage*, or *deterministic* policies. One can often obtain better performance than with one-shot policies by taking a fixed number of samples from each alternative in what is called a *first stage*, and then allocating a second stage of measurements based on the results. These are called *two-stage policies*. Three-stage and multistage policies are defined similarly. Finally, a policy that uses the results from all previous samples to make each measurement decision is called *fully sequential*. As we increase the number of stages and decrease the number of measurements per stage down to the limit established by the number of parallel processors, we allow greater efficiency but must contend with more complicated policies.

In the special case of $k = 2$ alternatives, the optimal one-shot policy was found in Ref. 16. This one-shot policy was shown to be optimal among the larger class of fully sequential policies with fixed measurement horizons in Ref. 14. If the prior variances and measurement variances are equal, this optimal policy is the one that allocates an equal number of measurements to each alternative. For more than two alternatives, however, finding optimal single-stage allocation policies is nontrivial, and finding optimal multistage and fully sequential policies is even more difficult.

We briefly review heuristic policies developed within the Bayesian decision-theoretic framework. Many earlier papers considered allocation rules in isolation, without considering the stopping rule. Using a decision-theoretic analysis and an asymptotic approximation, Chick and Inoue [17] introduce the LL and 0–1 allocation rules (for the linear loss and 0–1 loss functions

respectively), in both one-shot, two-stage, and multistage forms. In a different line of research motivated by Bayesian methods, a number of allocation rules have been developed under the collective name of optimal computing budget allocation (OCBA) in Refs 18–20 and other works. A fully sequential allocation rule derived using a one-step heuristic in a decision-theoretic dynamic-programming framework with known sampling variance was introduced in Ref. 16 and analyzed more fully in Ref. 14, where it was noted that the policy was a larger collection of myopic methods called *knowledge-gradient* (KG) methods. This allocation rule was extended to handle unknown sampling variance in Ref. 21 and given the name LL(1). A variety of adaptive stopping rules derived within a Bayesian framework were introduced in Refs 22–24, and Branke *et al.* [22] showed that good adaptive stopping rules perform much better than does stopping at a fixed time. Chick and Gans [13] considered both allocation and stopping rules for a natural extension of the R&S problem that includes discounting in time of the implementation payoff. A large empirical study of many of these policies was conducted in Ref. 25.

OTHER FORMULATIONS

We have focused on R&S for pedagogical reasons—it is simple enough to be easily and thoroughly explained while still exhibiting the core characteristics shared by all simulation optimization problems. We have further focused on Bayesian R&S because modern decision theory tends to be more interested toward Bayesian methods. Despite this focus on Bayesian R&S, there are other rigorous and useful formulations of the simulation optimization problem. Here we briefly describe two of them, the indifference-zone (IZ) formulation of the R&S problem, and BGO.

Indifference-Zone Ranking and Selection

The historical weight of the R&S literature employs a worst-case analysis known as the *indifference-zone* (IZ) formulation. Although

worst-case analyses have well-known drawbacks that have been highlighted within the decision-theoretic literature [11, Section 5.5], the IZ formulation represents an important approach within R&S.

In the IZ formulation of R&S, the decision maker’s goal is to implement the best alternative with a probability that exceeds a lower bound whenever the true configuration falls within a particular set of configurations. In detail, the IZ formulation begins by defining our loss function as

$$L(x^*, \theta) = \mathbf{1}_{\{x^* \in \arg \max_x \theta\}},$$

and the conditional risk of a policy is

$$R^\pi(\theta, \lambda) = \mathbb{P}^\pi \{x^* \in \arg \max_x \theta_x \mid \theta, \lambda\}.$$

This is also known as the *probability of incorrect selection*. The quantity $\text{PCS}^\pi(\theta, \lambda) = 1 - R^\pi(\theta, \lambda)$ is known as the *probability of correct selection*.

Then, rather than valuing a policy π according to its average-case performance under a prior, we specify a fixed parameter $\delta > 0$ and consider the policy’s worst-case performance over the set of configurations $\text{PZ}(\delta)$ defined by

$$\text{PZ}(\delta) = \left\{ \theta \in \mathbb{R}^k : \theta_{[1]} - \theta_{[2]} \geq \delta \right\},$$

where $[1], \dots, [k]$ are a permutation of the indices $1, \dots, k$ so that $\theta_{[1]} \geq \dots \geq \theta_{[k]}$. This set of configurations is called the *preference zone*. In addition to δ , we also specify a level $\alpha \in (0, 1 - 1/k)$, often 0.01 or 0.05, and require that π satisfies

$$\inf_{\theta \in \text{PZ}(\delta), \lambda \in \mathbb{R}_+^k} \text{PCS}^\pi(\theta, \lambda) \geq 1 - \alpha.$$

If a policy satisfies this, then we say that it satisfies the IZ guarantee for α and δ .

Whenever a configuration falls within the preference zone $\text{PZ}(\delta)$, the difference between best and all other alternatives is at least δ , and the decision maker is said to prefer this best alternative. Whenever the configuration falls outside the preference zone, the difference between the best and second best alternatives is small enough that the decision

maker is said to be indifferent to selecting the best. The IZ guarantee then guarantees that the decision maker selects the best with probability at least $1 - \alpha$, unless the configuration is such that he/she is indifferent. A more recent and stringent version of this formulation proposed in Ref. 26 additionally requires that the probability of selecting a “good” alternative (one whose sampling mean is within δ of the best) exceeds $1 - \alpha$ over all configurations $\theta \in \mathbb{R}^k$.

A large literature exists on the IZ formulation of the R&S problem. This literature develops policies that satisfy this IZ guarantee while at the same time taking samples as few as possible. This literature dates to the 1950s and the seminal works of Bechhofer [27,28]. For a more recent monograph, see Ref. 29, and for a current survey of the literature, see Refs 30 and 31.

Relative to Bayesian methods, the theoretical guarantee that IZ procedures offer is often quite appealing. This guarantee comes at a price, however, because IZ methods tend to be quite conservative, often taking many more samples than is strictly required to meet the guarantee for most configurations. This conservatism has two sources. First is the need to protect against extremely unfavorable configurations, even if these are seldom met in practice. This type of conservatism is intrinsic to the worst-case analysis used by the IZ formulation. Second, the existing procedures often over-sample, even under the most unfavorable configurations. This is because current methods for proving the IZ guarantee rely on inequalities that are often quite loose, especially for large numbers of alternatives. Recent efforts including those of Nelson *et al.* [32], Kim and Nelson [33], and Goldsman *et al.* [34] have greatly reduced but not eliminated this second type of conservatism. Thus, if one desires a well-understood statistical guarantee on the performance of the R&S procedure used, and is willing to spend some extra time on sampling, then IZ methods are appropriate. If instead, one desires good performance on average, and is willing to use a procedure whose performance is not as well characterized theoretically, then Bayesian methods are appropriate. For further discussion and extensive numerical

comparisons between Bayesian and IZ procedures, see Ref. 25.

Bayesian Global Optimization

R&S makes no assumptions about the relationship between different alternatives. In that problem, learning the value of one alternative tells us nothing about the value of other alternatives. This is a consequence of the independence of the alternatives’ true sampling means under the prior. In many applications of simulation optimization, however, the alternatives *are* related to each other. For example, in the classic problem of finding the best (s, S) inventory policy [1], two inventory policies with similar values for s and S usually perform similarly.

One can incorporate such information about the relationship between alternatives into the prior. One may replace the independent prior used in R&S with a prior under which the values of the alternatives are correlated. Conceptually, this is an easy extension of the Bayesian formulation of the R&S problem, but it presents many numerical and algorithmic challenges.

When the number of alternatives is finite, as it would be with the inventory policy example, one can use a multivariate normal prior. This case is considered in Ref. 35. When the space of alternatives is a multidimensional continuous space, as it would be when optimizing several continuous parameters, and the true sampling mean is a continuous function of these parameters, one can place a Gaussian process prior [36] on the unknown sampling mean. The resulting problem is known as the *Bayesian Global Optimization problem* (BGO).

In BGO, we have an infinite number of alternatives, but we have a characterization of their relationships to each other that allows efficient search for an optimum. Much of the literature on BGO assumes that the simulation is deterministic, but some of the literature considers stochastic simulation. Deterministic simulation is considered in Refs 37–43, and stochastic simulation in Refs 44 and 45. For broader issues in the use of Bayesian methods for inference on continuous functions produced as output from a simulator, see Refs 46–48.

A broad literature exists on global optimization beyond that, which is based on decision theory. Much of this literature assumes that function evaluations are free from noise—see the recent survey by Floudas and Gounaris [49] and also the recent book by Zhigljavsky and Žilinskas [50], both of which discuss noise-free BGO methods in this broader context. For a discussion of methods designed to handle noise in function evaluations see the surveys [7–10] mentioned in the introduction. Relative to other methods of global optimization, BGO requires more computational effort per measurement to decide which points to sample, but tends to find a good solution with fewer measurements. This is discussed and demonstrated numerically on a few example problems in Ref. 45. Thus, BGO tends to be more useful for optimizing complex long-running simulations, while other techniques are preferable for short-running simulations.

CONCLUSION

Simulation optimization is a difficult and important problem that is ubiquitous in OR, MS, and other fields. Decision theory offers us a way to understand how decisions should be made within simulation optimization algorithms. Better algorithms and deeper understanding of existing algorithms have resulted from the application of decision theory to these problems.

At the same time, many exciting challenges remain. Computing the optimal policy for all but the simplest problems, especially in sequential settings, remains practically impossible. In addition, existing work on simulation optimization has only begun to consider many aspects of the way that simulation optimization problems present themselves in practice, including aspects like risk aversion, the relationship between alternatives, steady-state simulations, common random numbers, and the difference between the simulation's output and the behavior of the real system. By understanding the decision-theoretic foundations of simulation optimization, we may more easily understand the proper response to these novel aspects

of the problem, and more easily design the algorithms of the future.

DECOMPOSITION ALGORITHMS FOR TWO-STAGE RECURSE PROBLEMS

JÁNOS MAYER

Institute for Operations Research,
University of Zurich, Zurich,
Switzerland

In this article decomposition methods for two-stage linear recourse problems with a finite discrete distribution are discussed. The following algorithms are presented: L-shaped decomposition, regularized decomposition, and stochastic decomposition. Variants for recourse-constrained problems and special cases including simple recourse with a random technology matrix are also considered. In connection with stochastic decomposition, the scope of which is not restricted to finite discrete distributions, algorithms for the continuous-distribution case are discussed briefly with references to the literature.

PROBLEM FORMULATION

We present decomposition algorithms for two-stage linear recourse problems with a finite discrete distribution of the random model parameters. Concerning the general case, which involves also continuous distributions, we have included a brief discussion in the section titled "Stochastic Decomposition" with references to the literature.

The basic problem formulation is the following:

$$\left. \begin{array}{l} \min_x \quad c^T x + \sum_{s=1}^S p_s Q_s(x) \\ Ax = b \\ x \geq 0, \end{array} \right\} \quad (1)$$

where $x \in \mathbb{R}^n$ is the vector of first-stage decision variables, A is an $(m \times n)$ matrix, and b and c are vectors with compatible dimensions. For the sake of simplicity of presentation, we assume that $B := \{x \mid Ax = b, x \geq 0\}$ is a nonempty and bounded set.

The second term in the objective function represents the expected recourse costs with $p_s > 0$ representing the scenario probabilities, $s = 1, \dots, S$, $\sum_{s=1}^S p_s = 1$. The *recourse function* $Q_s(x)$ stands for the recourse costs in scenario s , defined via the optimal objective value of *recourse subproblems* as follows:

$$Q_s(x) := \min_y \left. \begin{array}{l} (q^s)^T y \\ W^s y = h^s - T^s x \\ y \geq 0, \end{array} \right\} \quad (2)$$

where $y \in \mathbb{R}^{n_2}$ is the vector of recourse variables, W^s is an $(m_2 \times n_2)$ matrix, and the matrix T^s and the vectors h^s and q^s have compatible dimensions. W^s is called the *recourse matrix* and T^s is called the *technology matrix*. If W^s varies with s , then we have *random recourse* whereas *fixed recourse* means that $W^s \equiv W$, $\forall s$ holds, that is, the recourse matrix has no stochastic entries in this case. A model with fixed recourse is called a *complete recourse* model, if subproblem (2) has feasible solutions for any $x \in \mathbb{R}^n$ and for all $s = 1, \dots, S$. A special case of complete recourse is *simple recourse*, meaning that $n_2 = 2m_2$ and $W = (I, -I)$ hold with I standing for an $(m_2 \times m_2)$ unit matrix. A fixed-recourse model has *relatively complete recourse* if subproblem (2) is feasible for any $x \in B$ and for all s .

We also need the dual of the recourse subproblem, which reads

$$Q_s(x) := \max_u \left. \begin{array}{l} (h^s - T^s x)^T u \\ (W^s)^T u \leq q^s. \end{array} \right\} \quad (3)$$

It may be noted that the feasible domain of subproblem (3) does not depend on x . Therefore, if for some scenario s the dual problem is infeasible, this immediately implies that for any x the recourse subproblem (2) is either infeasible or otherwise the objective function is unbounded from below, and consequently our two-stage recourse problem (1) has no optimal solution. Therefore we assume in the sequel that subproblem (3) is feasible for all $s = 1, \dots, S$.

From the duality theory of linear programming (LP) [1], it follows under this assumption that for any $x \in \mathbb{R}^n$ and for any $s \in \{1, \dots, S\}$, the recourse subproblem (2) is either infeasible or otherwise it has an optimal solution.

Denoting the set of those x vectors for which the recourse subproblem (2) has feasible solutions by $K_s \subset \mathbb{R}^n$, it turns out that $Q_s(x)$ is a piecewise linear convex function, also called a *polyhedral function* defined over the polyhedral set K_s . Setting $K := \bigcap_s K_s$, it follows that the objective function of subproblem (1) is a finite-valued piecewise linear convex function over K . Adding the requirement $x \in K$, called *induced constraint*, to the constraint set of subproblem (1), the resulting problem can be classified as a convex nonsmooth optimization problem, with a polyhedral objective function. In fact, this is the starting point for a class of optimization algorithms for two-stage recourse problems. It may be noted that K is not explicitly given along with the dataset of the problem. Consequently, in the absence of relatively complete recourse, algorithms have to work with appropriate approximations of the set K .

It is easy to see that by introducing the auxiliary variables $y^1, \dots, y^S$, our two-stage recourse problem (1) can be equivalently formulated as an LP problem as follows:

$$\left. \begin{array}{ll} \min_{x, y^1, \dots, y^S} & c^T x + p_1(q^1)^T y^1 \dots + p_S(q^S)^T y^S \\ & \left. \begin{array}{ll} Ax & = b \\ T^1 x & + W^1 y^1 = h^1 \\ \vdots & \vdots \\ T^S x & + W^S y^S = h^S \\ x & \geq 0 \end{array} \right\} \\ & y^1 \geq 0 \dots y^S \geq 0. \end{array} \right\} \quad (4)$$

Having the above LP formulation, it is tempting to conclude that two-stage recourse problems with a finite discrete distribution can just be solved by utilizing general-purpose LP solvers applied directly to the LP problem (4). Current developments in LP-solver technology along with developments in computer hardware seem to justify this view. To see the weak point in this

reasoning, first note that the size of the constraint matrix of the LP problem (4) is $((m + S \cdot m_2) \times (n + S \cdot n_2))$. Considering a problem with altogether r stochastically independent random entries each of them having k realizations results in $S = k^r$ joint realizations, which grows exponentially with r . Thus, the combinatorial explosion quickly leads to practical problems that are numerically intractable with general-purpose solvers. For a recent experimental study that highlights the shortcomings of the above-mentioned naïve view, see Zverovich *et al.* [2].

Consequently, special-purpose algorithms that utilize the structure of the problem are needed. Considering the structure of the LP problem (4), we observe that the constraint matrix is a sparse matrix with a *dual block-angular* structure. In fact the dual problem of the LP problem (4) has a block-angular structure fitting into the scheme of the Dantzig–Wolfe decomposition [3] of LP and historically this was the first proposal for solving two-stage recourse problems with a finite discrete distribution provided by Dantzig and Madansky [4] in 1961. Concerning numerically efficient methods, the breakthrough came in 1969 with the L-shaped decomposition method of Van Slyke and Wets [5]. The basic idea is to apply the decomposition method of Benders [6] to the specially structured problem (4). The L-shaped method was the basis for the development of several further decomposition algorithms, like the regularized decomposition method of Ruszczyński [7] or stochastic decomposition algorithms of Higle and Sen [8]. Detailed presentations of these methods can be found in the following books: Birge and Louveaux [9, Chapter III, Sections 5 and 6], Kall and Mayer [10, Chapter 1, Sections 2.6–2.8 and Chapter 4, Section 4.2], Kall and Wallace [11 Sections 1.6.4 and 3.1–3.3], Mayer [12 Sections 1.2–1.3 and 3.1], and Prékopa [13 Chapter 12]. For the theoretical background see also Shapiro *et al.* [14] and the handbook edited by Ruszczyński and Shapiro [15]. For survey articles, see Wets [16] and Ruszczyński [17,18].

THE L-SHAPED METHOD

We give a short description of the method below under the simplifying assumption of *fixed recourse* and assuming that $q^s = q$, $\forall s$ holds. On this basis the algorithm for the general case can be derived in a straightforward manner. Under our assumptions the polyhedral feasible domain of the dual recourse subproblem (3) does not depend on s ; let us denote the finite set of vertices by $\mathcal{U}$ and the finite set of extremal rays of this polyhedral set by $\mathcal{V}$. From the duality theory of LP (see also the lemma of Farkas), it follows that the set $K_s \subset \mathbb{R}^n$ for which the s th recourse subproblem (2) has feasible solutions has the representation $\{x \mid v^T(h^s - T^s x) \leq 0, \forall v \in \mathcal{V}\}$ and for $x \in K_s$ the recourse function can be written as $Q_s(x) = \max_{u \in \mathcal{U}} u^T(h^s - T^s x)$. Using these observations, the two-stage recourse problem (1) can be written equivalently as

$$\min_{x, w} \left\{ \begin{array}{l} c^T x + w \\ \sum_{s=1}^S p_s u_s^T (h^s - T^s x) - w \leq 0, (u_1, \dots, u_S) \in \tilde{\mathcal{U}} \\ v^T (h^s - T^s x) \leq 0, v \in \mathcal{V} \\ x \in \mathcal{B} \end{array} \right\} \quad (5)$$

where $\tilde{\mathcal{U}}$ is the set of all S -tuples of vertices. Problem (5) is called the *full master problem* in the *aggregate form*. Since $\tilde{\mathcal{U}}$ and $\mathcal{V}$ are finite sets, this is an LP problem containing a huge amount of constraints, in general. The main idea of the L-shaped method of Van Slyke and Wets [5] is to generate a sequence of outer approximations to the feasible set via *constraint generation*. The constraints generated corresponding to the first type of constraints in the full master problem (5) will be called *optimality cuts*, while those of the second type will be termed as *feasibility cuts*. Let us denote by $\tilde{\mathcal{U}}^v$ the set of S -tuples of vertices corresponding to optimality cuts and denote by $\mathcal{V}^v$ the set of extremal rays corresponding to feasibility cuts, generated up to iteration $v \geq 1$. At $v = 0$ both sets are empty and $w = 0$ is fixed. The *relaxed master problem* at iteration v is the LP problem

$$\min_{x, w} \left\{ \begin{array}{l} c^T x + w \\ \sum_{s=1}^S p_s u_s^T (h^s - T^s x) - w \leq 0, (u_1, \dots, u_S) \in \tilde{\mathcal{U}}^v \\ v^T (h^s - T^s x) \leq 0, v \in \mathcal{V}^v \\ x \in \mathcal{B} \end{array} \right\} \quad (6)$$

At each iteration v , the following steps are carried out:

- S1. Solve the current relaxed master problem (6) leading to an optimal solution (x^v, w^v) . Because of the outer approximation, the optimal objective value $\underline{F}^v$ is a lower bound of the optimal objective value of the two-stage problem (1).
- S2. For $s = 1, \dots, S$ in turn solve the dual recourse subproblems (3) with $x = x^v$, by utilizing a simplex-type method. If for some s the objective function turns out to be unbounded on the feasible domain, add a feasibility cut to the relaxed master problem and go to the next iteration. Otherwise, that is, if optimal solutions were obtained for all $s = 1, \dots, S$, add an optimality cut, compute the expected value of the recourse function $Q(x^v) := \sum_{s=1}^S p_s Q_s(x^v)$, and continue with the next step. In this case, $\bar{F}^v := c^T x^v + Q(x^v)$ is an upper bound on the optimal objective value.
- S3. Check for optimality: if $Q(x^v) - w^v \leq 0$ then STOP. x^v is an optimal solution of the two-stage recourse problem (1) (in practical implementations the optimality check is carried out by employing a stopping tolerance $\varepsilon > 0$, of course). Otherwise continue with the next iteration.

It can be shown that the algorithm terminates in a finite number of iterations. The reason is that none of the feasibility cuts may reappear and if an optimality cut reappears then x^v is already optimal.

It may be noted that an optimality cut is only added to the relaxed master problem if the recourse subproblems had optimal solutions for all scenarios s . An alternative equivalent formulation of the two-stage recourse

problem (1) is the following LP problem:

$$\min_{x,w} \left. \begin{array}{l} c^T x + \sum_{s=1}^S p_s w_s \\ u^T(h^s - T^s x) - w_s \leq 0, u \in \mathcal{U} \\ v^T(h^s - T^s x) \leq 0, v \in \mathcal{V} \\ x \in \mathcal{B}. \end{array} \right\} \quad (7)$$

Problem (7) is called the *full master problem* in the *disaggregate form*. Applying the analogous constraint generation scheme as before leads to the *multicut* L-shaped method of Birge and Louveaux [19]. The relaxed master problem at iteration ν now reads as follows:

$$\min_{x,w} \left. \begin{array}{l} c^T x + \sum_{s=1}^S p_s w_s \\ u^T(h^s - T^s x) - w_s \leq 0, u \in \mathcal{U}^\nu \\ v^T(h^s - T^s x) \leq 0, v \in \mathcal{V}^\nu \\ x \in \mathcal{B}, \end{array} \right\} \quad (8)$$

where $\mathcal{U}^\nu$ consists of the vertices and $\mathcal{V}^\nu$ is the set of extremal rays that appeared up to iteration ν in the cuts. The difference in the algorithm is in Step 2, which for the multicut version runs as follows:

- S2. For $s = 1, \dots, S$ in turn solve the recourse subproblems (3) with $x = x^\nu$, by utilizing a simplex-type method. If for some s the objective function turns out to be unbounded on the feasible domain, add a feasibility cut to the relaxed master problem; otherwise add an optimality cut. If optimal solutions were obtained for all $s = 1, \dots, S$ then compute the expected value of the recourse function as before and continue with the next step. Otherwise continue with Step 1 of the next iteration.

Consequently, in the multicut version S cuts are added to the relaxed master problem in each of the iterations. This leads to a rapid growth of the number of constraints in the relaxed master problem.

In Step 2 of the L-shaped algorithm, S subproblems have to be solved for generating the cuts, which may become a computational bottleneck for large S . Either the dual

recourse subproblem (3) is solved directly or the recourse subproblem (2) is solved and the dual solution is derived from this. In the latter case, assuming $W^s = W$ and $q^s = q$, $\forall s$, we have to do with a sequence of LP problems that only differ in their right-hand sides. Algorithms for the solution of such sequences of LP problems have been proposed by Haugland and Wallace [20] and Gassmann and Wallace [21].

Step 2 also lends itself to parallel computing, and the subproblems can be solved in a parallel fashion by employing several processors. In fact, such variants have been developed by Linderoth and Wright [22,23].

Abaffy and Allevi [24] present a modification of the L-shaped method with aggregate cuts for fixed-recourse problems. Utilizing the special structure, they propose an algorithm with the ABS technique [25] applied to the LP problems arising in the decomposition algorithm, which leads to a substantial reduction in the overall number of arithmetic operations. It may be noted here that the acronym ABS is composed of the initials of the names of the authors Abaffy, Broyden and Spedicato, who have invented this class of methods.

For large S , the decomposition methods may become quite slow. Zhao [26] proposes to apply decomposition methods that are based on interior point (IP) techniques. Both the master problem and subproblems are smoothed via logarithmic barrier functions. The application of the IP technique basically means employing the very fast Newton method for the solution of the smoothed problems and results in polynomial-time algorithms; see Refs Boyd and Vandenberghe [27], Nesterov and Nemirovsky [28], Vanderbei [1] and Ye [29]. Berkelaar *et al.* [30] have developed an IP algorithm for solving two-stage recourse problems with random recourse. The algorithm is based on a homogeneous self-dual method where the decomposition is applied in the direction-finding subproblem of the algorithm.

In applications it may happen that the subproblems (2) are themselves large-scale LP problems; Thus, it makes sense to take approximate solutions for generating the optimality cuts, obtained, for example, by a primal-dual IP method. As long as the appr-

imate solution is dual feasible, this will generate valid cuts. Zakeri *et al.* [31] propose a convergent modification of the L-shaped method based on ε -subgradients and cuts, which are inexact in the above sense.

Inexact cuts form the basis of the level-decomposition method of Fábíán and Szóke [32], too. On the basis of a general algorithm for convex programming, in their method feasibility and optimality features are taken into account simultaneously. The probability distribution is approximated by coarser discrete distributions with increasing approximation accuracy across iterations, leading to inexact cuts in the decomposition method.

Because of similarities with the decomposition methods we also mention basis factorization methods utilizing the special structure of the LP problem (4) in the simplex method, when applied to the solution of the LP problem (4). The first method of this type has been proposed by Strazicky [33]; for further algorithms in this Class, see Birge and Louveaux [19, Section 5.6].

Takriti and Ahmed [34] consider two-stage recourse problems with suitably chosen variability measures in the objective and propose a variant of the L-shaped method for the solution of such problems.

REGULARIZED DECOMPOSITION

In the sequence of iterations of the L-shaped method, the number of constraints is steadily growing in the relaxed master problem. This growth is especially rapid in the variant with disaggregate cuts where S new cuts are added in each iteration. In the L-shaped method, there is no reliable strategy for dropping redundant cuts, without destroying the finite termination property of the algorithm. Consequently, with increasing number of iterations the resulting large number of constraints may cause numerical difficulties in the relaxed master problem. In addition to this, the relaxed master problem becomes increasingly ill-conditioned because of almost parallel cuts added especially in the vicinity of the optimal solution.

Another unfavorable property of the L-shaped algorithm is the following: even if the starting point x^0 is already close to the

optimal solution of the two-stage recourse problem (1), after adding cuts in Step 2 the subsequent points x^k , $k \geq 1$ may be far away from the optimum and it may take a large number of iterations till the iterates come back to the neighborhood of the optimal solution.

For overcoming these difficulties, Ruszczyński [7] proposed to apply regularization to the relaxed master problem in the disaggregate form leading to the following objective function in the relaxed master problem (8):

$$c^T x + \alpha \|x - z^v\|^2 + \sum_{s=1}^S p_s w_s,$$

which now contains a regularizing term $\alpha \|x - z^v\|^2$, where z^v is the current *candidate solution*, α is a scaling factor, and $\|\cdot\|$ is the Euclidean norm. α is kept zero till the first candidate solution is found; afterward it is either set to a constant $\alpha > 0$ or it is used as a control parameter varying across iterations in a finite interval $[\alpha_1, \alpha_2]$ with $\alpha_1 > 0$. The first candidate solution will be the solution of the relaxed master problem after an optimality cut has been added for the first time. The idea is that the current candidate solution is kept over iterations, $x^{v+1} := x^v$, as long as the approximation to the objective function is not good enough in the vicinity of it. The criterion for changing the candidate to $z^v := x^v$ in an iteration v without feasibility cuts is

$$\sum_{s=1}^S p_s (u_s^v)^T (h^s - T^s x^v) \leq \sum_{s=1}^S p_s w_s^v,$$

where $(u_1^v, \dots, u_S^v)$ are the vertices corresponding to the optimality cuts added at iteration v . Besides this, further rules for changing the candidate solution have also been suggested, based on approximations; see Ruszczyński [7] and Ruszczyński and Święt anowski [35].

It may be noted that the regularized relaxed master problem is now a quadratic programming problem of the constrained least squares type. Reference [7] also contains a proposal for solving it, based on an active-set strategy.

An outstandingly important feature of the regularized decomposition method is that it

allows for cut-dropping. After having solved the current regularized relaxed master problem, all cuts having zero Lagrange multipliers at the optimal solution can be dropped. Thus, the number of cuts in the regularized relaxed master problems to solve is at most $n + 2S$ throughout the iterations. It can be shown that the regularized decomposition method terminates in a finite number of iterations.

Alternative regularization techniques are based on trust region constraints around the solution from the previous iteration. Linderoth and Wright [22,23] propose to add a trust-region constraint to the relaxed master problem having the form $\|x - x^{v-1}\|_\infty = \max_i |x_i - x_i^{v-1}| < \Delta_v$. The choice of the ∞ -norm allows for an equivalent reformulation of the relaxed master problem as an LP problem. In fact, the trust-region constraint can be written equivalently as

$$\begin{aligned} |x_i - x_i^{v-1}| &< \Delta_v, \quad \forall i \\ \Leftrightarrow -\Delta_v &< x_i - x_i^{v-1} < \Delta_v, \quad \forall i, \end{aligned}$$

resulting in linear constraints. The regularized version is embedded into an L -shaped method for parallel computation.

STOCHASTIC DECOMPOSITION

In Step 2 of the L -shaped method, S LP problems have to be solved. For S really large this step will be impossible to carry out. Having, for instance, a recourse problem with 10 stochastically independent random entries, each of them having 10 realizations, the number of joint realizations S will be $S = 10^{10}$ for which Step 2 becomes impossible to carry out. Under such circumstances stochastic decomposition techniques can be used. For these methods fixed recourse and $q^s = q$ is assumed.

Infanger [36,37] proposes an algorithm where, in each iteration v of the L -shaped method, in Step 2 a separate sample is drawn from the distribution. On the basis of this sample, a Monte Carlo approximation of the cuts is computed employing variance reduction via importance sampling. The sample size is increased in each of the

iterations. As in the L -shaped method, upper and lower bounds are utilized for the stopping rule. The difference is that the bounds are in this case random variables themselves and the stopping rule involves Student's t -test for checking whether the difference of these bounds is less than the stopping tolerance, on a given significance level. Since the algorithm involves sampling within the L -shaped method, it belongs to the class of *internal* sampling algorithms (also called *interior* sampling methods).

The basic representant of the class of internal sampling algorithms is the stochastic decomposition method (SD) of Higle and Sen [8,38]. While in Infanger's method a separate whole sample is drawn at each of the iterations, in the SD method just one sample point is drawn per iteration. Thus a single sample is being built as the iterations progress.

For discussing the SD algorithm, we assume complete recourse. We also assume that $Q_s(x) \geq 0$ holds for all $x \in \mathcal{B}$ and for all s ; for a weaker assumption, see Higle and Sen [38]. In the SD method the sample is drawn in a step-by-step manner and in each of these steps an appropriately modified iteration step of the L -shaped method is carried out. At iteration v the next sample element (h_v, T_v) is drawn and in Step 2 of the L -shaped algorithm a single recourse subproblem (3) is solved corresponding to $s = v$. Thus, during the course of the algorithm a single sample is being built that has sample size v at iteration v . The next optimality cut is computed on the basis of the following inequality:

$$\frac{1}{v} \sum_{s=1}^v u_s^T (h^s - T^s x) \leq \frac{1}{v} \sum_{s=1}^v Q_s(x),$$

where $((h_1, T_1), \dots, (h_v, T_v))$ is the sample drawn up to iteration v and $u_s \in \mathcal{U} \forall s$ holds. On the right-hand side of this inequality stands the actual Monte Carlo approximation of the expected recourse function, based on the current sample, while the left-hand side represents the optimality cut in the aggregate form to be added in this iteration. It may be noted that the inequality is valid for any $u_s \in \mathcal{U}$. The idea

is to store the optimal dual vertices up to iteration $\nu - 1$ while u_ν comes from the solution of the recourse subproblem. For each $s = 1, \dots, \nu - 1$ a dual vertex corresponding to the highest $u_s^T(h^s - T^s x)$ value for $x = x^\nu$ is chosen. The principle behind this procedure is to generate a cut as tight as possible.

The cuts generated in the previous iterations, corresponding to Monte Carlo approximations from previous steps, may become invalid in the current iteration. Consequently, those cuts need to be updated. Let $\nu \geq 2$ and $\kappa < \nu$. The basis for an update is the following inequality

$$\begin{aligned} \frac{1}{\nu} \sum_{s=1}^{\kappa} u_s^T(h^s - T^s x) &\leq \frac{1}{\nu} \sum_{s=1}^{\kappa} Q_s(x) \\ &\leq \frac{1}{\nu} \sum_{s=1}^{\nu} Q_s(x), \end{aligned}$$

which holds for any $u_s \in \mathcal{U}$ because of LP duality and because of the assumption $Q_s(x) \geq 0$, for all $x \in \mathcal{B}$. At the earlier iteration κ a cut involving the function

$$\frac{1}{\kappa} \sum_{s=1}^{\kappa} u_{s(\kappa)}^T(h^s - T^s x),$$

has been generated, with $u_{s(\kappa)} \in \mathcal{U}$, $s = 1, \dots, \kappa$, being the dual vertices chosen at iteration κ . Owing to the inequality above, replacing this cut function by

$$\frac{1}{\nu} \sum_{s=1}^{\kappa} u_{s(\kappa)}^T(h^s - T^s x),$$

results in a valid cut at iteration $\nu > \kappa$. It may be noted that with increasing ν the earlier cut, based on a smaller sample size κ , becomes gradually phased out. It is easy to see that this transformation can be carried out as follows: at each of the iterations $\nu \geq 2$, all of the previous cuts are multiplied by $\frac{\nu-1}{\nu}$.

The main problem concerning stochastic algorithms, like the SD method outlined so far, is to identify appropriate stopping rules. The authors employ *incumbent solutions* for this reason. Initially the incumbent solution is just the solution of the expected value problem. At each iteration it is checked whether

the current optimal objective function value of the relaxed master problem is sufficiently lower than the approximate objective value at the incumbent solution. If yes, the current solution x^ν of the relaxed master problem becomes the new incumbent solution. The cut corresponding to the incumbent solution is updated at each iteration. On the basis of a subsequence of iterations where the incumbent changes, several stopping rules are proposed by the authors; see Higle and Sen [38].

The method as outlined above is based on aggregate cuts. An SD method employing disaggregate cuts has been developed by Higle *et al.* [39]. As in the deterministic L -shaped method, the accumulation of redundant cuts induces numerical difficulties in the relaxed master problem. To avoid this, Higle and Sen [40] and Yakowitz [41] developed a regularized SD method that allows for dropping redundant cuts in a safe manner, similar to the deterministic regularized decomposition method.

The monograph of Higle and Sen [38] contains a detailed description of the SD method and its variants discussed above. Sen *et al.* [42] present an overview on recent developments concerning the SD algorithm. It may be noted that, by its very nature, SD is also applicable for two-stage recourse problems with continuous distributions.

For providing information to the interested reader, we briefly discuss two algorithmic approaches for the case with continuous distributions, although they do not belong to the class of decomposition methods.

Sample average approximation (SAA) methods are *external* sampling methods. A single sample is drawn and considering it as a special discrete distribution the resulting problem is solved, for example, by applying the L -shaped method. Important related problems include the choice of a proper sample size and validation analysis. For a detailed presentation, see Shapiro [43] and the references therein.

Successive discrete approximation methods construct a sequence of discrete approximations to the distribution. The idea is to partition the support of the distribution into a finite number of subsets, and to

construct an approximate discrete distribution by taking the conditional expectations and conditional probabilities corresponding to this partition. The resulting two-stage recourse problems with discrete distributions are solved and based on the results, a refinement of the partition is carried out for the next (refined) approximation. An outstanding feature of these algorithms is that at each iteration deterministic lower and upper bounds are provided for the optimal objective value of the original problem. For details, see Kall and Stoyan [44], Frauendorfer and Kall [45], and Frauendorfer [46]. For an introduction and implementation of these methods, see also Kall and Mayer [10] and Mayer [12].

SPECIAL CASES AND RECOURSE CONSTRAINTS

An important special case of the general two-stage recourse problem is simple recourse. Let us first assume that in the simple recourse problem only the right-hand side is stochastic, meaning that $q^s = q$ and $T^s = T$ hold for all s . For this case, very efficient solution algorithms are available, as discussed in Birge and Louveaux [19], Kall and Wallace [11], and Wets [47,16]. The basic observation is that in this case the recourse function becomes separable in the variables $\chi := Tx$ and an equivalent LP can be formulated that has a much smaller size than the LP (4). This LP can be solved very efficiently; consequently, in this case there is no need to apply decomposition methods. We emphasize that having a deterministic technology matrix T is essential for obtaining the small-scale equivalent LP.

Considering simple recourse problems with a *random technology matrix*, the simplifications outlined above do not carry over to this case. Klein Haneveld and Van der Vlerk [48] observed that, for such problems, solving the recourse subproblems in Step 2 of the L -shaped method essentially reduces to just checking signs of the components of the vector $h^s - T^s x^v$, which yields a great speedup in the overall method. They apply the algorithm for stochastic optimization problems with integrated chance constraints. Künzi-Bay

and Mayer [49] applied this technique for solving stochastic optimization problems involving the minimization of Conditional Value-at-Risk (CVaR:), which can be reformulated as a simple recourse problem with a random technology matrix. The authors report on a speedup of several *orders of magnitude* in the computing time when it is compared with solving the equivalent LP by general-purpose commercial LP solvers.

Another practically important special case is network recourse, which means that the recourse subproblems are network-flow problems. A numerically efficient variant of the L -shaped method has been proposed by Wallace [50] for such problems.

Stochastic optimization problems with a *recourse constraint* have been introduced and first studied by Higle and Sen [51]. Such problems have the form

$$\left. \begin{array}{l} \min_x \quad c^T x \\ d^T x + \sum_{s=1}^S p_s Q_s(x) \leq \gamma \\ x \in \mathcal{B}, \end{array} \right\}$$

with γ prescribed. Yakowitz [52] developed an algorithm based on exact penalty functions for this problem class. Kall and Mayer propose in Chapter 4, Section 4.2 of Ref. 10 an application of the L -shaped method for the solution of such problems. In Section 4.4 of the same chapter a numerically efficient L -shaped algorithm is presented for problems with a CVaR constraint, as a special case.

INTRODUCTION

Decomposition methods are techniques for exploiting the tractable substructures of an integer program in order to obtain improved solution procedures. In particular, the goal is to derive improved methods of bounding the optimal solution value, which can then be used to drive a branch-and-bound algorithm (see **Branch-and-Bound Algorithms**). Such methods are the preferred solution approaches for a wide range of important models arising in practice and have also been the basis for solution approaches for many well-known combinatorial problems. A small sample of the problems for which decomposition approaches have been proposed in the literature includes the multicommodity flow problem [1], the cutting stock problem [2,3], the traveling salesman problem [4], the generalized assignment problem (GAP) [5,6], the bin packing problem [7], the axial assignment problem [8], the Steiner tree problem [9], the single-machine scheduling problem [10], the graph coloring problem [11], and the capacitated vehicle routing problem [12–15].

To expose the desired substructure, a common approach is to relax a set of “complicating constraints.” This is the approach taken by the Dantzig–Wolfe Decomposition (DWD), Lagrangian relaxation, and cutting-plane methods (see **Dantzig–Wolfe Decomposition; Lagrangian Optimization for LP**). Substructure can also be

exposed by fixing the values of a set of variables, that is, considering restrictions of the original problem. This is the approach taken by Benders’ decomposition (see **Benders Decomposition**). This article reviews decomposition methodologies based on relaxation of constraints and examines how they are used to solve mixed integer linear programs (ILPs). For a broader overview, including variable restriction methods, see Vanderbeck and Wolsey [16].

To simplify the exposition, we consider only pure ILPs with finite upper and lower bounds on all variables, so that the set of feasible solutions is finite. The framework can easily be extended to more general settings. For the remainder of the article, we consider an ILP instance whose feasible set is the integer vectors contained in the polyhedron $Q = \{x \in \mathbb{R}^n \mid Ax \geq b\}$, where $A \in \mathbb{Q}^{m \times n}$ is the constraint matrix and $b \in \mathbb{Q}^m$ is the right-hand side vector. Let $\mathcal{F} = Q \cap \mathbb{Z}^n$ be the set of all *feasible solutions* to the ILP and let the polyhedron $\mathcal{P}$ be the convex hull of $\mathcal{F}$. In terms of this notation, the ILP is to determine

$$\begin{aligned} z_{\text{IP}} &= \min_{x \in \mathcal{F}} \{c^\top x\} = \min_{x \in \mathcal{P}} \{c^\top x\} \\ &= \min_{x \in \mathbb{Z}^n} \{c^\top x \mid Ax \geq b\}, \end{aligned} \quad (\text{IP})$$

where $c \in \mathbb{Q}^n$. By convention, $z_{\text{IP}} = \infty$ if $\mathcal{F} = \emptyset$ (the problem is infeasible).

THE PRINCIPLE OF DECOMPOSITION

Computing bounds is an essential element of the branch-and-bound algorithm, which is the most effective and most commonly used method for solving such mathematical programs. Bounds are often computed by solving a *bounding subproblem* that is a tractable relaxation of the original problem. The most commonly used bounding subproblem is the linear programming (LP) relaxation. The LP relaxation is often too weak to be effective in solving difficult ILPs. Decomposition

techniques based on constraint relaxation can be used to obtain improved bounding subproblems.

To apply the principle of constraint decomposition, we consider the relaxation of (IP) defined by

$$\begin{aligned} \min_{x \in \mathcal{F}'} \{c^\top x\} &= \min_{x \in \mathcal{P}'} \{c^\top x\} \\ &= \min_{x \in \mathbb{Z}^n} \{c^\top x \mid A'x \geq b'\}, \end{aligned} \quad (\text{R})$$

where $\mathcal{F} \subset \mathcal{F}' = \{x \in \mathbb{Z}^n \mid A'x \geq b'\}$ for some $A' \in \mathbb{Q}^{m' \times n}, b' \in \mathbb{Q}^{m'}$, and $\mathcal{P}'$ is the convex hull of $\mathcal{F}'$. As usual, we assume that there exist practical¹ algorithms for optimizing over and/or separating from $\mathcal{P}'$. With respect to $\mathcal{F}'$, let $[A'', b''] \in \mathbb{Q}^{m'' \times n''}$ be a set of additional *side constraints* needed to describe $\mathcal{F}$; that is, $[A'', b'']$ is such that $\mathcal{F} = \{x \in \mathbb{Z}^n \mid A'x \geq b', A''x \geq b''\}$. We denote by $\mathcal{Q}'$ the polyhedron described by the inequalities $[A', b']$ and by $\mathcal{Q}''$ the polyhedron described by the inequalities $[A'', b'']$. Hence, the initial LP relaxation is the linear program defined by $\mathcal{Q} = \mathcal{Q}' \cap \mathcal{Q}''$, and the *LP bound* is given by

$$\begin{aligned} z_{\text{LP}} &= \min_{x \in \mathcal{Q}} \{c^\top x\} \\ &= \min_{x \in \mathbb{R}^n} \{c^\top x \mid A'x \geq b', A''x \geq b''\}. \end{aligned} \quad (\text{LP})$$

Note that $[A', b']$ and $[A'', b'']$ are often a partition of the rows of $[A, b]$ into a set of “nice constraints” and a set of “complicating constraints,” but this is not a strict requirement.

Optimization and/or separation over $\mathcal{P}'$ may be more tractable than over $\mathcal{P}$ for a number of reasons. First, it may simply be that $\mathcal{P}'$ has a known structure for which we have well-developed techniques. This first case arises frequently when the original problem is formed by adding side constraints to a well-studied base problem. Second, the resulting relaxation may decompose because of identifiable block-diagonal structure of the matrix A' . In this case, optimization over

$\mathcal{P}'$ can be accomplished by optimizing over each of these blocks independently (possibly in parallel). This second case arises when the constraints of A'' are constraints that link a collection of otherwise independent subsystems (see Example 2). A particular case in which decomposition is often applied very effectively is when A' consists of a set of identical blocks. In this case, the optimization problem over $\mathcal{P}'$ reduces to optimization over just one of the blocks. This can be seen as a way of eliminating symmetry present in the original problem and is one of the primary reasons why decomposition methods work well on certain classes of combinatorial problems.

DECOMPOSITION TECHNIQUES

In this section, we discuss three techniques for computing bounds on z_{IP} , which are based on the principle of decomposition. In the section titled “Relationship of the Techniques,” we show that these methods are very closely related.

Lagrangian Relaxation

For a given vector of *dual multipliers* $u \in \mathbb{R}_+^{m''}$, the *Lagrangian relaxation* [17–20] of (IP) is given by

$$z_{\text{LR}}(u) = \min_{s \in \mathcal{F}'} \{(c^\top - u^\top A'')s + u^\top b''\}. \quad (\text{LR})$$

It is then easily shown that $z_{\text{LR}}(u)$ is a lower bound on z_{IP} . The problem

$$z_{\text{LD}} = \max_{u \in \mathbb{R}_+^{m''}} \{z_{\text{LR}}(u)\} \quad (\text{LD})$$

of maximizing this bound over all choices of dual multipliers is a dual to (IP) called the *Lagrangian dual* (LD) and also provides a lower bound z_{LD} , which we call the *LD bound*. A vector of multipliers $\hat{u}$ that yield the largest bound is called *optimal (dual) multipliers*.

The Lagrangian function $z_{\text{LR}}(u)$ is piecewise linear concave in u and hence can be maximized using the subgradient algorithm to obtain z_{LD} . Alternatively, it can also be

¹The term *practical* is not defined rigorously, but denotes an algorithm with a “reasonable” average-case running time.

solved by rewriting it as the equivalent linear program

$$z_{LD} = \max_{\alpha \in \mathbb{R}, u \in \mathbb{R}_+^{m'}} \left\{ \alpha + u^\top b'' \mid \alpha \leq (c^\top - u^\top A'') s \right. \\ \left. \forall s \in \mathcal{F}' \right\}. \quad (\text{LDLP})$$

Of course, this linear program has a large number of constraints and so must be solved by means of a cut generation algorithm (known as *Kelley's cutting-plane algorithm* [21]). In either approach to solving the LD, most of the computational effort goes into evaluating $z_{LR}(u)$ (called the *Lagrangian subproblem*) for a given sequence of dual multipliers u . This is an optimization problem over $\mathcal{P}'$ and can be solved effectively by assumption. Both these approaches are described in detail in Nemhauser and Wolsey [22].

Dantzig–Wolfe Decomposition

The approach of DWD [23] is to reformulate (IP) by implicitly requiring the solution to be a member of $\mathcal{F}'$, while explicitly enforcing the inequalities $[A'', b'']$. Relaxing the integrality constraints on the variables from the original formulation, we obtain the linear program

$$z_{DW} = \min_{\lambda \in \mathbb{R}_+^{\mathcal{F}'}} \left\{ c^\top \left(\sum_{s \in \mathcal{F}'} s \lambda_s \right) \mid \right. \\ \left. A'' \left(\sum_{s \in \mathcal{F}'} s \lambda_s \right) \geq b'', \right. \\ \left. \sum_{s \in \mathcal{F}'} \lambda_s = 1 \right\}. \quad (\text{DWLP})$$

We call this LP the *Dantzig–Wolfe linear program* (DWLP), though it is frequently referred to as the *master problem* in the literature. Although the number of columns in this linear program is $|\mathcal{F}'|$, it can be solved by column generation². In each iteration of such a method, a restricted version of (DWLP), commonly referred to as the *restricted master*

problem (RMP), is solved to obtain optimal primal and dual solutions. The column generation subproblem is to generate a new column that has negative reduced cost with respect to the dual solution $\hat{u}$ of the RMP (if one exists). This is equivalent to evaluating $z_{LR}(\hat{u})$, as in (LR).

Because the DWLP is solved by column generation, methods that use a DWLP to obtain bounds within a branch-bound-bound algorithm are sometimes referred to generically as *column generation methods* [24,25]; see also the article **Column Generation**. In fact, most column generation algorithms for solving integer programs, even those for which the column generation derives directly from a “natural” formulation, can be seen as arising from the application of DWD to an underlying “compact” model, even if that compact model is not always first formulated explicitly [26]. Branch-and-bound approaches in which column generation is used to obtain a bound in each node are known as *branch-and-price* algorithms [6,27,28]; see also the article **Branch-Price-and-Cut Algorithms**.

It is easy to verify that (DWLP) is an LP dual of (LDLP), which immediately shows that $z_{DW} = z_{LD}$; see Parker and Rardin [29] for a detailed treatment of this fact. Hence, z_{DW} is a valid lower bound on z_{IP} that we call the *DW bound*. Note that the dual variables in (DWLP) correspond to the dual multipliers from (LR). Furthermore, if we combine the members of $\mathcal{F}'$ using $\hat{\lambda}$, we obtain an optimal solution

$$\hat{x}_{DW} = \sum_{s \in \mathcal{F}'} s \hat{\lambda}_s \quad (\text{MAP})$$

to the DWLP, which we call the *optimal fractional solution* corresponding to $\hat{\lambda}$. Note that (MAP) provides a mapping of each point in the feasible set of the Dantzig–Wolfe reformulation to a unique member of $\mathcal{P}' \cap \mathcal{Q}''$. This mapping will be extensively used in the methods discussed in the section titled “Branch, Price, and Cut.” Using this mapping, we can see that $z_{DW} = c^\top \hat{x}_{DW}$. Since $\hat{x}_{DW}$ must lie within $\mathcal{P}' \subseteq \mathcal{Q}'$ and also within $\mathcal{Q}''$, this shows that $z_{DW} \geq z_{LP}$.

²Note that we can equivalently replace $\mathcal{F}'$ with the extreme points of $\mathcal{P}'$.

Figure 1. Polyhedra (Example 1: SILP).

Cutting-Plane Method

Although the cutting-plane method [30–33] is not usually thought of as a decomposition method, it can in fact be viewed as such. Under our assumption that the separation problem associated with $\mathcal{P}'$ can effectively be solved, a cutting-plane method in which inequalities describing $\mathcal{P}'$ (i.e., the facet-defining inequalities) are generated dynamically can be implemented. By separating the solutions to a series of augmented LP relaxations from $\mathcal{P}'$, as in the usual cutting-plane approach, the initial LP relaxation can be iteratively augmented to obtain the *CP bound*

$$z_{CP} = \min_{x \in \mathcal{P}'} \{c^\top x \mid A''x \geq b''\}. \quad (\text{CPLP})$$

Note that $\hat{x}_{DW}$, as defined in (MAP), is an optimal solution to this augmented linear program. Hence, the CP bound is equal to both the DW bound and the LD bound. We refer to the augmented linear program above as the *cutting-plane linear programming* (CPLP).

Although we have described the cutting-plane method here as being based on our ability to solve the separation problem exactly over a single polyhedron $\mathcal{P}'$ containing $\mathcal{P}$, one of the advantages of the cutting-plane method over the first two

decomposition approaches is that it is possible, in practice, to simultaneously generate valid inequalities from multiple decompositions. This can further improve the bound beyond what can be achieved with either of the other two methods alone. Furthermore, it is also possible to obtain a valid bound without solving the separation problem *exactly*; that is, the procedure does not have to guarantee to generate a valid inequality violated by the solution to the current LP relaxation whenever one exists. More details on these relationships between the methods are presented in the next section. In the section titled “Advanced Methods,” we discuss how to integrate cutting-plane methods with other decomposition techniques.

RELATIONSHIP OF THE TECHNIQUES

The following well-known result showed that the three approaches just described are simply three different algorithms for computing the same quantity.

Theorem 1 [Geoffrion 34]. $z_{IP} \geq c^\top \hat{x}_{DW} = z_{LD} = z_{DW} = z_{CP} = \min \{c^\top x \mid \mathcal{P}' \cap \mathcal{Q}''\} \geq z_{LP}$.

We refer to the quantity $z_D = \max\{c^\top x \mid \mathcal{P}' \cap \mathcal{Q}''\}$ as the *decomposition bound*. The proof of this result follows directly from the

discussion of the section titled “Decomposition Techniques.” Example 1 illustrates the application of the decomposition principle on a simple two-variable ILP and Fig. 1 demonstrates computation of the bound graphically.

Example 1 [SILP]. Consider the following ILP in two variables:

$$\begin{aligned}
 & \min x_1 \\
 & \text{s.t. } 7x_1 - x_2 \geq 13, & (1) \\
 & \quad x_2 \geq 1, & (2) \\
 & \quad -x_1 + x_2 \geq -3, & (3) \\
 & \quad -4x_1 - x_2 \geq -27, & (4) \\
 & \quad -x_2 \geq -5, & (5) \\
 & \quad 0.2x_1 - x_2 \geq -4, & (6) \\
 & \quad -x_1 - x_2 \geq -8, & (7) \\
 & \quad -0.4x_1 + x_2 \geq 0.3, & (8) \\
 & \quad x_1 + x_2 \geq 4.5, & (9) \\
 & \quad 3x_1 + x_2 \geq 9.5, & (10) \\
 & \quad 0.25x_1 - x_2 \geq -3, & (11) \\
 & \quad x \in \mathbb{Z}^2. & (12)
 \end{aligned}$$

In this example, we let

$$\begin{aligned}
 \mathcal{P} &= \text{conv} \left\{ x \in \mathbb{R}^2 \mid x \text{ satisfies (1) -- (12)} \right\}, \\
 \mathcal{Q}' &= \left\{ x \in \mathbb{R}^2 \mid x \text{ satisfies (1) -- (6)} \right\}, \\
 \mathcal{Q}'' &= \left\{ x \in \mathbb{R}^2 \mid x \text{ satisfies (7) -- (11)} \right\}, \text{ and} \\
 \mathcal{P}' &= \text{conv} \left(\mathcal{Q}' \cap \mathbb{Z}^2 \right).
 \end{aligned}$$

In Fig. 1a, we show the associated polyhedra, where the set of feasible solutions $\mathcal{F} = \mathcal{Q}' \cap \mathcal{Q}'' \cap \mathbb{Z}^2 = \mathcal{P}' \cap \mathcal{Q}'' \cap \mathbb{Z}^2$ and $\mathcal{P} = \text{conv}(\mathcal{F})$. Figure 1b depicts the continuous approximation $\mathcal{Q}' \cap \mathcal{Q}''$, while Fig. 1c shows the improved approximation $\mathcal{P}' \cap \mathcal{Q}''$. For the objective function in this example, optimization over $\mathcal{P}' \cap \mathcal{Q}''$ leads to an improvement over the LP bound obtained by optimization over $\mathcal{Q}$.

It is easy to see that we can only have $z_D > z_{LP}$ when $\mathcal{P}' \subset \mathcal{Q}'$. This is formalized in the following corollary of Theorem 1.

Corollary 1. *If $\mathcal{Q}'$ is an integral polyhedron, then $z_D = z_{LP}$.*

It is important to point out that this result does not depend on the objective function—if $\mathcal{Q}'$ is integral, then $z_D = z_{LP}$ for *any* objective function vector. On the other hand, the converse is not true. If $\mathcal{Q}'$ is not integral, we might still have $z_D = z_{LP}$ for *certain* objective functions. In the following example, we illustrate the result of the corollary.

Example 2 [GAP]. The GAP is that of finding a minimum cost assignment of n tasks to m machines such that each task is assigned to precisely one machine subject to capacity restrictions on the machines. With each possible assignment, we associate a binary variable x_{ij} , which, if set to one, indicates that machine i is assigned to task j . For ease of notation, let us define two index sets $M = \{1, \dots, m\}$ and $N = \{1, \dots, n\}$. Then an ILP formulation of GAP is as follows:

$$\begin{aligned}
 & \min \sum_{i \in M} \sum_{j \in N} c_{ij} x_{ij}, \\
 & \sum_{j \in N} w_{ij} x_{ij} \leq b_i \quad \forall i \in M, & (13) \\
 & \sum_{i \in M} x_{ij} = 1 \quad \forall j \in N, & (14) \\
 & x_{ij} \in \{0, 1\} \quad \forall i, j \in M \times N.
 \end{aligned}$$

In this formulation, Equation (14) ensures that each task is assigned to exactly one machine. Inequalities (13) ensure that for each machine, the capacity restrictions are met.

One possible decomposition of GAP is to let the relaxation be defined by the assignment constraints as follows:

$$\mathcal{Q}' = \{x_{ij} \in \mathbb{R}^+ \mid \forall i, j \in M \times N \mid x \text{ satisfies (14)}\}$$

and

$$\mathcal{Q}'' = \{x_{ij} \in \mathbb{R}^+ \forall i, j \in M \times N \mid x \text{ satisfies (13)}\}.$$

For this decomposition, the polytope $\mathcal{Q}'$ is integral, that is, $\mathcal{Q}' = \text{conv}(\mathcal{Q}' \cap \{0, 1\}^{M \times N})$. Hence, according to Corollary 1, the decomposition bound z_D is equal to that of the LP relaxation. If we instead choose a relaxation defined by the capacity constraints, we get the following:

$$\mathcal{Q}' = \{x_{ij} \in \mathbb{R}^+ \forall i, j \in M \times N \mid x \text{ satisfies (13)}\}$$

and

$$\mathcal{Q}'' = \{x_{ij} \in \mathbb{R}^+ \forall i, j \in M \times N \mid x \text{ satisfies (14)}\}.$$

In this case, the relaxation is a set of knapsack problems. These knapsack polyhedra do not have the integrality property, so the decomposition bound *may* be better than the LP bound. This is also an example of a decomposable subproblem—the optimization over $\mathcal{P}'$ reduces to a set of independent knapsack problems, one for each machine, which can be solved effectively in practice.

It should now be clear that these three methods are very closely related. In each of the three methods, we are given a polyhedron $\mathcal{P}$ over which we would like to optimize, along with two polyhedra that contain $\mathcal{P}$, the polyhedron $\mathcal{Q}''$, which has a small description and can be represented explicitly, and the polyhedron $\mathcal{P}'$, with a much larger description that must be represented implicitly. The conceptual difference between DWD, Lagrangian relaxation, and the cutting plane method is that both DWD and Lagrangian relaxation utilize an *inner representation* of $\mathcal{P}'$, generated dynamically by solving the corresponding optimization problem, whereas the cutting-plane method relies on an *outer representation* of $\mathcal{P}'$, generated dynamically by solving the corresponding separation problem. In this framework, most dynamic methods for solving ILPs can be viewed as decomposition methods.

In fact, there are even deeper connections between decomposition methods based on outer approximation and the more traditional methods based on inner representation

that serve to shed further light on the relationship. Recall that after solving (DWLP), we can obtain the optimal fractional solution $\hat{x}_{DW}$ corresponding to the optimal solution $\hat{\lambda}$ using the mapping (MAP). Note that $\hat{x}_{DW}$ is a convex combination of members of $\mathcal{F}'$. In particular, it is a combination of the members of the set $\{s \in \mathcal{F}' \mid \hat{\lambda}_s > 0\}$, which we will refer to as the *decomposition* of $\hat{x}_{DW}$ arising from $\hat{\lambda}$. It can be shown that $\hat{x}_{DW}$ must always be contained in a proper face of $\mathcal{P}'$ that we can characterize precisely as follows. Consider the set

$$S = \{s \in \mathcal{F}' \mid (c^\top - \hat{u}^\top A'')s = (c^\top - \hat{u}^\top A'')\hat{s}\}, \quad (15)$$

where $\hat{s}$ is some member of the decomposition (and hence corresponds to a basic variable in an optimal solution to (DWLP)). The following theorem states that the set S must contain all members of the decomposition. The proof is straightforward and can be found in Ralphs and Galati [35].

Theorem 2. $\{s \in \mathcal{F}' \mid \hat{\lambda}_s > 0\} \subseteq S$.

In fact, we can show something stronger. The set S is comprised exactly of those members of $\mathcal{F}'$ corresponding to columns of the (DWLP) with reduced cost zero, so we have the following theorem. The proof is again straightforward and can be found in Ralphs and Galati [35].

Theorem 3. $\text{conv}(S)$ is a face of $\mathcal{P}'$ and contains $\hat{x}_{DW}$.

An important consequence of this result is the following corollary, which states that the face of optimal solutions to (CPLP) is contained in $\text{conv}(S) \cap \mathcal{Q}''$.

Corollary 2. If F is the face of optimal solutions to (CPLP), then $F \subseteq \text{conv}(S) \cap \mathcal{Q}''$.

Hence, the convex hull of the decomposition is a subset of $\text{conv}(S)$ that contains $\hat{x}_{DW}$ and can be thought of as a surrogate for the face of optimal solutions to (CPLP).

Figure 2. Illustration of bounds for different cost vectors.

As noted earlier, $\text{conv}(S)$ is typically a proper face of $\mathcal{P}'$. It is possible, however, for $\hat{x}_{DW}$ to be an inner point of $\mathcal{P}'$. In this case, illustrated graphically in Fig. 2a, $z_{DW} = z_{LP}$ and DWD does not improve the bound. All columns of (DWLP) have reduced cost zero and any extremal member of $\mathcal{F}'$ could be made a member of the decomposition. Hence, the effectiveness of the procedure is reduced and the chosen relaxation may be too weak. A necessary condition for an optimal fractional solution to be an inner point of $\mathcal{P}'$ is that the dual value of the convexity constraint in an optimal solution to the (DWLP) be zero. This result is further examined in the next section.

A second case of potential interest is when $F = \text{conv}(S) \cap \mathcal{Q}''$, illustrated graphically in Fig. 2b. This condition can be detected by examining the objective function values of the members of the decomposition. If they are all equal, then any member of the decomposition that is contained in $\mathcal{Q}''$ (if one exists) must be optimal for the original ILP, since it is feasible and has objective function value equal to z_D . In this case, all constraints of (DWLP) *other than* the convexity constraint must have dual value zero, since removing them does not change the optimal solution value. The more typical case, in which F is

a proper subset of $\text{conv}(S) \cap \mathcal{Q}''$, is shown in Fig. 2c.

ADVANCED METHODS

As previously mentioned, the cutting-plane method has a number of advantages in practice over traditional decomposition approaches. Within the framework presented here, the generation of valid inequalities can be interpreted as a dynamic tightening of either $\mathcal{Q}''$ or $\mathcal{P}'$. We will focus on the former interpretation and discuss two methods that employ either (DWLP) or (LD) as the bounding subproblem, but also integrate generation of valid inequalities.

We first consider the basic steps of the cutting-plane method, assuming the problem at hand is feasible and bounded. To begin, we construct an initial LP relaxation and solve it. We then perform the separation step, attempting to generate inequalities valid for $\mathcal{P}$ but violated by the resulting solution. If successful, we add these inequalities to the LP relaxation, hoping to improve the bound. This procedure is iterated until no more violated inequalities are found. The most important step is that of separation, which results in a tightening of $\mathcal{Q}''$ and (hopefully) an improved bound.

Decomposition with Cut Generation

1. Construct the initial bounding subproblem P^0 and set $i \leftarrow 0$.

$$z_{CP} = \min_{x \in \mathcal{P}'} \{c^\top x \mid A''x \geq b''\}$$

$$z_{LR} = \max_{u \in \mathbb{R}_+^m} \min_{x \in \mathcal{P}'} \{(c^\top - u^\top A'')x + u^\top b''\}$$

$$z_{DW} = \min_{\lambda \in \mathbb{R}_+^s} \{c^\top (\sum_{s \in \mathcal{F}'} s\lambda_s) \mid A''(\sum_{s \in \mathcal{F}'} s\lambda_s) \geq b'', \sum_{s \in \mathcal{F}'} \lambda_s = 1\}$$

2. Solve P^i to obtain a valid lower bound z^i .
3. Generate a set of *improving inequalities* $[D^i, d^i]$ valid for $\mathcal{P}$.
4. If valid inequalities were found in Step 3, form the bounding subproblem P^{i+1} by setting $[A'', b''] \leftarrow [\frac{A''}{D^i}, \frac{b''}{d^i}]$. Then, set $i \leftarrow i + 1$ and go to Step 2.
5. If no valid inequalities were found in Step 3, then output z^i .

Figure 3. Basic outline of the dynamic decomposition method.

In principle, this procedure can be generalized by replacing (CPLP) with either (DWLP) or (LD) as the bounding subproblem. The steps of this generalized method are shown in Fig. 3. The important step is Step 3, that of generating a set of *improving inequalities*; that is, inequalities valid for $\mathcal{P}$ that when added to the description of the $\mathcal{P}'$ result in an increase in the computed bound. Aside from Step 3, the method is straightforward. Steps 1 and 2 are performed as in a traditional decomposition framework. Step 4 is accomplished by simply adding the newly generated inequalities to the list $[A'', b'']$ and reforming the appropriate bounding subproblem.

It is important to point out that the generalized methods described in Fig. 3 require that we can solve the subproblem (LR) for *any* objective function. In some cases, the algorithm used for solving the subproblem may be efficient only when the objective function has certain structure. In such cases, it may only be possible to integrate generation of classes of valid inequalities whose addition does not destroy the required structure of the subproblem.

In the cutting-plane method, techniques for generating valid inequalities typically measure the potential effectiveness of adding a given valid inequality by the degree to which it violates $\hat{x}_{DW}$, since violation of $\hat{x}_{DW}$ is a necessary condition for an inequality to be improving. It is not clear, however, what

criteria should be used to measure potential effectiveness if the bounding subproblem is either (DWLP) or (LD). In the next two sections, we discuss these two cases in more detail.

Branch, Price, and Cut

We first consider using (DWLP) as the bounding subproblem in the procedure of Fig. 3, a procedure we call *price and cut*. When employed as the bounding procedure in a branch-and-bound framework, the overall technique is called *branch, price, and cut* and has been studied by a number of authors [10, 36–38]. Simultaneous generation of columns and valid inequalities is difficult in general because the addition of valid inequalities may destroy the structure of the column generation subproblem (for a discussion, see van den Akker *et al.* [10]). Having solved (DWLP), however, we can easily recover an optimal solution to (CPLP) using (MAP) and try to generate improving inequalities using standard separation methods for $\mathcal{P}$. Because the generation of these valid inequalities takes place in the space of the original formulation, it does not destroy the structure of the column generation subproblem (with the possible exception of the objective function, as discussed above). Hence, the approach enables dynamic generation of valid inequalities while still retaining the bound improvement

and other advantages yielded by a DWD. It is important to note, however, that the case of block decompositions with identical subproblems presents unique challenges to the implementation of price and cut, since collapsing the identical subproblems into a single subproblem means that the mapping (MAP) cannot be used to provide a unique optimal fractional solution; see Vanderbeck [28] for a discussion.

The same bound improvement obtained in price and cut could be realized in the cutting-plane method by adding the generated inequalities directly to (CPLP). Despite the apparent symmetry, there is one fundamental difference between the cutting-plane method and price and cut. An optimal solution to (DWLP) provides a decomposition of $\hat{x}_{\text{DW}}$ (MAP) into a convex combination of members of $\mathcal{F}'$. In particular, the weight on each member of $\mathcal{F}'$ in the combination is given by the optimal decomposition.

An important observation is that an inequality can be improving only if it is violated by at least one member of the decomposition. This follows easily from the fact that the degree of violation of $\hat{x}_{\text{DW}}$ is a convex combination of the degrees of violation of each member of the decomposition. In some cases, it is much easier to separate members of $\mathcal{F}'$ from $\mathcal{P}$ than to separate arbitrary real vectors. In fact, it is easy to find polyhedra for which the problem of separating an arbitrary real vector is difficult, but the problem of separating a solution to a given combinatorial relaxation is easy. This notion has been discussed in the literature in several contexts [14,39,40] and leads to a separation technique that can be embedded within price and cut [35]. The idea is to replace direct separation of the fractional point (which may be difficult) with separation of members of the decomposition, which act as surrogates. Given a decomposition, the efficiency of this procedure depends both on the cardinality of the decomposition (which must be less than or equal to $\dim(\mathcal{P}') + 1$) and the time required to separate members of $\mathcal{P}'$ from $\mathcal{P}$.

Branch, Relax, and Cut

We now move on to discuss the dynamic generation of valid inequalities when the bounding subproblem is (LD). When employed in a branch-and-bound framework, the overall method is called *branch, relax, and cut* and has also previously been studied by several authors (see Lucena [39] for a survey). Solving the LD as the linear program (LDLP) is equivalent to solving (DWLP), so, in this case, the methods just discussed apply directly without modification. We assume from here on that the LD is solved in the form (LD), using subgradient optimization.

Suppose we have solved (LD) to obtain $\hat{u}$, a vector of optimal multipliers and $\hat{s} = \operatorname{argmin} z_{\text{LR}}(\hat{u})$. As before, let $\hat{\lambda}$ be an optimal decomposition and $\hat{x}_{\text{DW}} = \sum_{s \in \mathcal{F}'} \hat{\lambda}_s \hat{s}$ be an optimal fractional solution. The main consequence of using subgradient optimization to solve (LD) is that we do not obtain the primal solution information available to us with both the cutting-plane method and price and cut. This means there is no obvious way of constructing an optimal fractional solution or verifying that any generated valid inequalities would be violated by such a solution. We can, however, attempt to separate the solution to the Lagrangian relaxation (LR), which is a member of $\mathcal{F}'$, from $\mathcal{P}$. Note that again, we are taking advantage of our ability to separate members of $\mathcal{F}'$ from $\mathcal{P}$ effectively. If successful, we immediately “dualize” this new constraint by adding it to $[A'', b'']$. This has the effect of introducing a new dual multiplier and slightly perturbing the objective function used to solve the Lagrangian relaxation.

As with both the previously discussed methods, the difficulty with relax and cut is that the valid inequalities generated by separating $\hat{s}$ from $\mathcal{P}$ may not be improving, as Guignard first observed in her work [41]. As we have already noted, we cannot verify that generated inequalities are violated by an optimal fractional solution, which is the usually employed necessary condition for an inequality to be improving. To deepen our understanding of the potential effectiveness of the valid inequalities generated during relax and cut, we now further examine the relationship between $\hat{s}$ and $\hat{x}_{\text{DW}}$.

From the reformulation of the LD as the linear program (LDLP), we can see that each constraint binding at an optimal solution corresponds to an alternative optimal solution to the Lagrangian subproblem with multipliers $\hat{u}$. The binding constraints of (LDLP) correspond to variables of (DWLP) with reduced cost zero, so it follows immediately that the set of all alternative solutions to the Lagrangian subproblem with multipliers $\hat{u}$ is the set S from Equation (15).

Because $\hat{x}_{\text{DW}}$ is both an optimal solution to (CPLP) and is contained in $\text{conv}(S)$, it also follows that

$$c^\top \hat{x}_{\text{DW}} = (c^\top - \hat{u}^\top A'') \hat{x}_{\text{DW}} + \hat{u}^\top b''.$$

In other words, the penalty term in the objective function of the Lagrangian subproblem (LR) serves to rotate the original objective function so that it becomes parallel to the face $\text{conv}(S)$, while the constant term $\hat{u}^\top b''$ ensures that $\hat{x}_{\text{DW}}$ has the same cost with respect to both the original and the Lagrangian objective function. This is shown in Fig. 2c.

The fundamental connection between relax and cut and price and cut is that solving (DWLP) produces a *set* of alternative optimal solutions to the LD, at least one of which must be violated by a given improving inequality. This yields a verifiable necessary condition for a generated inequality to be improving. Relax and cut, on the other hand, produces only one member of this set, though possibly at a much lower computational cost. Even if improving inequalities exist, it is possible that none of them are violated by $\hat{s}$, especially if $\hat{s}$ has a small weight in the optimal decomposition. As in price and cut, when $\hat{x}_{\text{DW}}$ is an inner point of $\mathcal{P}'$, the decomposition does not improve the bound and all members of $\mathcal{F}'$ are alternative optimal solutions to the Lagrangian subproblem. This situation is depicted in Fig. 2a. In this case, separating $\hat{s}$ is unlikely to yield an improving inequality.

CONCLUSION

Decomposition algorithms capitalize on our knowledge of identifiable substructure in

a given integer programming model. This knowledge could be in the form of either a method of optimizing over or separating from the convex hull of solutions to a given relaxation. In the former case, an inner representation of the convex hull can be implicitly used in either a DWD or Lagrangian relaxation framework. In the latter case, an outer representation can be used in a cutting-plane framework. The use of advanced techniques that integrate generation of valid inequalities with the use of either DWD or Lagrangian relaxation is an attempt to achieve the “best of both worlds.” Implementations of these advanced algorithms are becoming more common, and this trend is sure to continue as more software tools become available.

DEFINING OBJECTIVES AND CRITERIA FOR DECISION PROBLEMS

JASON R. W. MERRICK
Statistical Sciences and
Operations Research,

University, Richmond,
Virginia

INTRODUCTION

Clemen [1] defines an objective as “a specific thing that you want to achieve.” We write an objective in terms of the noun describing the quality of an alternative that we value and a verb indicating the direction in which we would like to improve this quality. For instance, in making many business decisions, we value the monetary profits that an alternative may lead to and we wish to maximize these profits. Thus, profit is the quality of an alternative and maximize is the verb indicating our direction of preference. We may also wish to maximize the market share for our products, minimize impacts on the environment, and maximize customer satisfaction.

An objective is a reason to value one alternative over another. Without values, all alternatives are equivalent and there is no decision. As values are more fundamental to a decision than alternatives, Keeney [2] suggests that we should consider values before we consider available alternatives. Considering our values gives us the ability to conceptualize the structure of a decision by considering the objectives a decision maker seeks to achieve. We can then consider whether such objectives are a means to an end or fundamental to the current decision.

However, in the end we wish to achieve our objectives by taking the best action or choosing the best alternative. To find the best alternative, we must consider the widest range of alternatives and discriminate between them

in the most comprehensive and thoughtful way. We want to have as wide a range of focus as possible to expand our search for the best alternative [3]. Keller and Ho [4] point out that we may use heuristics and biases to simplify the task of generating alternatives. Using the availability heuristic, we may simply recall the alternatives most readily available in memory. Alternatively, we may use the representativeness heuristic and recall a list of alternatives that are representative of similar decisions. Each of these heuristics narrows the focus of our consideration to just those alternatives readily available in memory. Jungermann *et al.* [5] show that the best way to expand our focus is to have the largest set of objectives possible. Gettys *et al.* [6] show that the set of objectives should be as complete and hierarchical as possible if we are to generate high utility actions or alternatives. Leon [7] claims five advantages to using a comprehensive set of objectives in choosing amongst alternatives.

1. Alternatives with more innovative characteristics are considered.
2. The range of alternatives considered becomes wider.
3. The future consequences of decisions are taken into account.
4. Alternatives are integrated, which at first glance would not be considered.
5. More desirable consequences are considered.

The purpose of this article is to examine how well decision makers can generate a comprehensive set of objectives and to offer methods to improve the generation process.

We start by introducing a framework for thinking about and classifying objectives in the section titled “The Decision Context.” We then examine the problems faced in the generation of objectives and examine methods for lessening these problems in the section titled “What is Good Set of Objectives?”

THE DECISION CONTEXT

Keeney uses the concept of a *decision context* to explain the decisions that people make. A decision context consists of a decision maker's set of alternatives and the objectives that the decision maker is attempting to achieve when choosing. The objectives can be categorized as means, fundamental, and strategic. A *means objective* is one way to achieve another objective. A *fundamental objective* is an objective that governs a decision maker's choice in a particular decision context. A *strategic objective* is one that reflects the long term goals of a decision maker's organizational setting; many decisions in an organization may affect performance on a strategic objective. Keeney [8] states that misunderstanding the decision context is a common mistake in making trade-offs between alternatives.

We do not wish to measure achievement on an objective that is just one means to achieve what we value. Nor do we wish to measure achievement on an objective that is affected by decisions other than this one. Thus, we evaluate each alternative by how well they achieve the decision maker's fundamental objectives. However, that is not to say that means objectives and strategic objectives are not useful. Means objectives give us different means to achieving our fundamental objectives, so they are useful in developing alternatives that we may not otherwise think of. Strategic objectives are useful to make sure that each decision problem is aimed at our overall values.

Our objectives will also change depending on the decision context that we consider. Consider choosing a car to buy. Two fundamental objectives might be minimizing purchase cost and minimizing monthly fuel costs. However, if we broaden the decision frame to how to get to work, then we extend the alternatives to include different cars and different routes, as well as public transportation and carpooling options. Now minimizing monthly commuting costs becomes fundamental for the broader decision context.

It is important to understand whose values and perspectives should be considered. Keeney [8] uses the example of a public

utility company and two major objectives: minimize electricity costs to ratepayers and maximize returns to company shareholders. If faced with alternatives that lead to a low cost and a low return or a high cost and a high return, it is important to understand whose perspective is being considered. The ratepayers would prefer the former, the company shareholders would prefer the latter, and the public utility commission would prefer a trade-off between the two.

Keeney notes that it is also important to understand the timeline of the decision. Suppose you are deciding between two job offers. Two important objectives would be to maximize salary and minimize hours worked per week. Would you choose a job with a high salary that required 80 h of work each week or one with a lower salary that only required 50 h a week? Timeline is important in this decision. Many people would choose the high salary job with long work hours if this lasted for a limited number of years or months, like residency for a doctor or early associate work for lawyers and management consultants. However, this choice would be less desirable if there was no end to the long work hours.

WHAT IS A GOOD SET OF OBJECTIVES?

Keeney [9] proposes five criteria for a good set of objectives.

1. Completeness
2. Nonredundancy
3. Conciseness
4. Specificity
5. Understandability

The set of objectives must be complete in the sense that all possible angles of the problem are considered. If we omit an important objective, then we may choose the wrong alternative, or at least not foresee all the consequences of our chosen alternative. For example, consider buying a car and considering purchase cost, ongoing costs, visual appeal, reliability, drivability, and cargo space, but not comfort.

We wish to avoid redundant objectives, as this will lead to double counting the benefits

of an alternative. For example, in our car example we should not include maximize miles per gallon and minimize monthly fuel costs as objectives, as these quantities overlap. However, a car could have a high miles per gallon rating, but require an expensive grade of fuel. In this case, we could use maximize miles per gallon and minimize price per gallon of fuel required. Or, we could simplify to minimize monthly fuel costs.

A set of objectives must be concise. A set that is too large can lead to “paralysis by analysis,” as we are bogged down by considering the many objectives. Imagine you are hungry and are deciding where to eat dinner; considering a hundred objectives would probably be more frustrating than helpful.

We must be able to measure how well each alternative performs on achieving each objective or at least compare the alternatives under each objective. This means that our objectives must be specific and understandable to remove ambiguity in their measurement. Some examples of objectives that are hard to measure are maximize aesthetic appeal or minimize pain level. Research has been performed that has led to reliable measures of even these objectives by specific definitions, but the level of effort required should be commensurate with the importance of the decision being made. Developing attributes to measure objectives will be discussed at more length in the article titled ***Problem Structuring for Multicriteria Decision Analysis Interventions*** in this encyclopedia.

The set of objectives should also be decomposable so that we may consider each part separately, simplifying the judgment task and leading to a better appraisal of the alternatives. This criterion requires that the performance of an alternative on each objective can be judged independently of all other objectives. For instance, in choosing a hotel room, can you consider comfort and size of the room separately, or we must define our objectives as the comfort of the furniture and the size of the room to decompose the pieces of this assessment. This concept will be discussed at length in the article titled ***Problem Structuring for Multicriteria Decision Analysis Interventions*** in this encyclopedia.

PROBLEMS WITH GENERATING OBJECTIVES

We wish to determine the decision maker’s objectives for a given decision context. The objectives are generated through interviews with decision makers and stakeholders. However, decision makers are not generally good at stating the objectives that they are trying to achieve. Bond *et al.* [10] note that decision makers attempt to simplify their environment and avoid the actual complexity of the decisions they make. This means that the objectives they offer are cued by “an incomplete mental representation of the situation” [10].

Bond *et al.* performed three studies to test the ability of decision makers to generate objectives. In each case, the experimenters first asked the subjects to generate a list of objectives for a specified decision context. The subjects were then given a pregenerated list of objectives that was considered complete. The experimenters asked the subjects to check the objectives that they saw as important and then to indicate which of the list were objectives they had developed before seeing it. The objectives that they had checked off but did not develop before seeing the list were called the *recognized* objectives. The objectives that they checked off and had developed before seeing the list were called the *self-generated* objectives. Lastly, they were asked to assess the importance of all the objectives that they had checked off, both recognized and generated.

In the first experiment, MBA students were asked to consider the choice of a program to join. They completed the exercise in one sitting, ending with a ranking of the objectives. In all, the study obtained 62 usable responses. The second experiment was identical to the first in all but one aspect. The ranking of objectives was asked one week later to reduce any bias toward the self-generated objectives. Seventy usable responses were obtained. For the third experiment, the decision context changed to the choice of a summer internship. The MBA students completed the same tasks, but the experimenters gave them one week to generate their own list of objectives. The ranking of objectives was also replaced with

a rating on a scale from 1 (not important) to 10 (extremely important). Twenty-eight responses were obtained.

For the first experiment, the subjects generated 7.4 objectives on average, while 7.6 were recognized. For the second experiment, the averages were 5.9 self-generated objectives and 7.7 recognized. For the third experiment, an average of 6.8 objectives were self-generated and 7.9 were recognized. The mean number of recognized objectives is statistically significantly higher than the mean number of self-generated objectives in each experiment.

In the first experiment, 71% of the subjects overlooked at least one of their top five objectives and 79% in the second. Interestingly, 35% of subjects did not self-generate their most important objective in the second experiment compared to 10% in the first experiment. In the third experiment, the average importance rating for self-generated objectives (7.4) was significantly higher than the average importance for the recognized objectives (6.8). Thus, while a significant number of objectives were not self-generated, the subjects did self-generate objectives that are more important. However, the difference in the importance rating is not that large in a practical sense.

In a final real-world case study, Bond *et al.* [10] reanalyzed the results of a professional elicitation performed for Seagate Software [11]. The professional facilitator worked with 12 individual decision makers in the company to generate their list of objectives, and then the results were combined into a complete value hierarchy containing 39 specific objectives grouped into 8 categories. On average, the subjects generated at least one specific objective in 5.16 of the 8 categories. They generated an average of 14.17 specific objectives of the 39, which is 36%. Only one subject generated more than half (20 or more). Thus, these three experiments and one case study show that decision makers will not generate a complete list of objectives on their own.

Bond *et al.* [12] reanalyzed the experimental results from their earlier study [10]. The master lists of objectives for each of the three experiments were categorized into four sets of related objectives. The number

of generated objectives and the number of recognized objectives were counted by group for each subject. The authors concluded that the number of self-generated objectives was significantly less than the total number of checked objectives in each category, so the subjects were not thinking with sufficient depth in any category. However, the authors also found that the category in which each subject generated the most objectives had significantly more than would be expected if the generation was independent of category. The category for which each subject generated the least objectives also had significantly less than would be expected. Thus, the subjects were not thinking with sufficient breadth, concentrating on a few categories and ignoring others. This implies an anchoring effect within a subset of the possible categories.

Leon [7] describes a similar study, but instead compares a decision maker's ability to generate objectives when they focus on specific alternatives or when they focus on values and objectives. The subjects of the generation study were 28 psychology students with some training in decision analysis. The experimenter asked the subjects to generate objectives to use in choosing amongst advanced elective courses. A randomly assigned 14 students were asked to generate objectives to help in the decision while considering a predefined list of elective courses. These were the alternative-focused group. The remaining students were asked to generate objectives using a set of value-focused questions adapted from Keeney [2] and were called the *value-focused* group. Each subject was then asked whether each objective they generated was a specific objective or whether it was a general objective made up of lower level specific objectives.

The value-focused group generated a total of 28 different objectives, while the alternative-focused group generated 22. Leon [7] then developed representative value hierarchies for each group consisting of the average number of general objectives and the average number of specific objectives, with the actual objectives chosen by ranking the number of decision makers in the group that generated them. Thus, the value-focused representative hierarchy contained the top

three most prevalent general objectives and the top nine most prevalent specific objectives in that group. The alternative-focused representative hierarchy contained one overall general group and the top five most prevalent specific objectives in that group. Thus, the value-focused group developed a larger set of objectives and organized them hierarchically. Qualitative consideration of the hierarchies revealed that all the issues covered in the alternative-focused representative hierarchy were covered in the value-focused representative hierarchy, but not vice versa. Thus, the value-focused hierarchy was more complete.

In a follow-on study, Leon asked a different set of 30 decision makers to assess the two representative hierarchies from the first study. The second set of subjects assessed which of the two hierarchies better met five criteria for a useful hierarchy. In each case, the results were statistically significantly in favor of the value-focused hierarchy. The 30 decision makers were also asked to rate the two hierarchies in terms of completeness, ability to operationalize, conciseness, and understandability. The results were statistically significantly in favor of the value-focused hierarchy in all but conciseness, where the results were not significant in either direction.

In summary, decision makers are not good at generating a large and complete set of objectives. They get anchored in a few categories of objectives, not thinking with sufficient breadth. They also do not think with sufficient depth in any category. However, they are better if they focus on values than on alternatives. The methods discussed in the next section are aimed at broadening the consideration leading to a more complete set of objectives. Leon [7] and Bond *et al.* [10] both show that combining the objectives generated by a number of individuals leads to the most complete set. Thus, we do not hold individual interviews with individual decision makers, but discuss their decisions as a group. This allows the various decision makers to increase each other's perspective of the situation and broaden each other's view. This also leads to a more complete set of objectives.

METHODS FOR GENERATING OBJECTIVES

Keeney [13] offers the following list of devices to use in generating objectives:

1. *A Wish List.* What do you want? What do you value? What should you want?
2. *Alternatives.* What is a perfect alternative, a terrible alternative, some reasonable alternative? What is good or bad about each?
3. *Problems and Shortcomings.* What is wrong or right with your organization? What needs fixing?
4. *Consequences.* What has occurred that was good or bad? What might occur that you care about?
5. *Goals, Constraints, and Guidelines.* What are your aspirations? What limitations are placed upon you?
6. *Different Perspectives.* What would your competitor or your constituency be concerned about? At some time in the future, what would concern you?
7. *Strategic Objectives.* What are your ultimate objectives? What are your values that are fundamental?
8. *Generic Objectives.* What objectives do you have for your customers, your employees, your shareholders, and yourself? What environmental, social, economic, or health and safety objectives are important?
9. *Structuring Objectives.* Follow means–ends relationships: why is that objective important, how can you achieve it? Use specification: what do you mean by this objective?
10. *Quantifying Objectives.* How would you measure achievement of this objective? Why is objective A three times as important as objective B?

Let us consider a facilitation performed by the author to see the benefits of following this list [14]. The goal of the facilitation was to understand the objectives of decision makers in an oil shipping company as they related to safety performance. We will overview the techniques that we used in our interviews.

1. *A Wish List.* We asked a group of crew members from various vessels what they look for when they join a new crew; if they were to describe a perfectly operating vessel and crew, what would it look like. The crew described a perfect vessel and crew, and we examined the factors that they saw exemplified such a vessel. We also examined what exemplified an unsafe vessel and crew.
2. *Alternatives.* We asked the crew members about vessels they had worked on and previous crews they had worked with; what was good or bad about them? The crew members told good and bad stories about crews they had worked with and what factors affected their performance.
3. *Problems and Shortcomings.* We talked through various problems they encountered and what could be done to avoid them.
4. *Consequences.* We asked the crew what accidents or near misses had occurred on vessels they served on and what could have helped avoid these events.
5. *Goals, Constraints, and Guidelines.* We examined safety procedures in the company and safety regulations, both federal and international, to see what objectives they set minimum standards for.
6. *Different Perspectives.* We included bridge crew, deck crew, and engineering crew in our interviews. We included senior and junior personnel. We also included vessel inspectors and shore side managers.
7. *Strategic Objectives.* This includes working through means to achieving reduction in accidents, near misses, human errors, mechanical failures, and other precursor events.
8. *Generic Objectives.* We considered basic considerations of the company's mission statement and other generic policies.
9. *Structuring Objectives.* We considered each generated objective and what it was a means to achieving. We then followed the chains of means-ends

relationships to generate additional objectives. Training arose frequently in the discussions, but training is a means to achieving improved performance, so we examined different training programs and what they sought to achieve.

10. *Quantifying Objectives.* Here we considered how one could measure each objective to further specify what each meant. We also considered the metrics they had used and the data they collected to see what objectives they measured.

Leon [7] offers a list of questions to help decision makers discern their objectives. The relationship between the questions and the list of devices above is apparent on inspection.

1. What do you look for in a ____?
2. What is really important when you think about using and enjoying ____?
3. What do you want to obtain?
4. What need is not covered now that would be covered?
5. Once acquired, what are the desirable consequences of its use and enjoyment?
6. What are the undesirable consequences?
7. What are the restrictions on its acquisition?
8. If there were no restrictions, which alternative would you choose? What characteristic makes it the one you would choose?
9. Which alternative would you definitely not choose and why?
10. How does the use of a help you in terms of your objectives or fundamental values in life?
11. When you think of the choice, what aspects do you think should be taken into account?
12. When you think of several alternatives, which differences are the most obvious?
13. From the point of view of users, if you had to carry out a study to their satisfaction, which aspects would you take into account?

Interviews with decision makers are not the only way to develop objectives. Parnell *et al.* [15] calls decision maker and stakeholder interviews the “Platinum Standard” technique. Other approaches would be to base the development on documentation approved by the decision makers on vision, policy, or strategy, “Gold Standard,” or to use interviews with people who will inform or assist the actual decision maker, “Silver Standard.” The same devices can be used while examining the literature for objectives or interviewing people who provide decision support, but do not make the actual decision.

Bond *et al.* [12] test techniques for improving the breadth and depth of objectives generation. In their first experiment, subjects were asked to generate a list of objectives for writing their dissertation. They were then asked to expand on their list in a second session and given category cues to attempt to broaden their consideration. In the second experiment, subjects were asked to generate objectives for choosing an MBA program and given category cues and example objectives in each category in a single session. In the third experiment, subjects were asked to generate objectives for choosing an internship. They were then asked to expand on their list in a second session by adding a specified number of additional objectives. Thus, the first and third experiments had two sessions, the first unaided and the second using different interventions. The intervention was used straightaway in the second experiment. In the first two experiments the intervention was category cues, while in the third experiment the intervention was asking for specific numbers of additional objectives.

The results of the three experiments revealed several interesting conclusions. First, providing example objectives in the second experiment anchored the subjects and hindered their generation of objectives. Secondly, providing the category cues straightaway was ineffective, but it was effective when used in a second session asking for an expanded list. Thirdly, asking for a specific number of additional objectives was effective in the third experiment, whereas just asking for more is not. Fourthly, stating that subjects are generally able to add more

objectives sets an expectation of performance that the subjects strive to achieve. As subjects in these experiments are generally able to generate 30–50% of the master list, asking for as many again as the first session appears appropriate.

AN EXAMPLE FROM ENVIRONMENTAL MANAGEMENT

A set of objectives was developed for the Upham Brook Watershed to demonstrate how this technique can be applied to a complex environmental management problem [16,17]. The interdisciplinary team, composed of faculty members and graduate students from Virginia Commonwealth University assisted by a hydrologist from the U.S. Geological Survey (USGS), a water quality regulator from DEQ, a community organizer, and a wetlands specialist, all participated in the development of the model. The group met every two weeks for eight months, each session lasting 2h. The author of this article facilitated the sessions and supplied the understanding of the techniques used. While the group had significant substantive expertise, the members of the team were not stakeholders. Thus, this is a silver standard example in the terminology of Parnell *et al.* [15].

The first step in the process is to define the overall objective for the project. The overall objective selected was “Maximize the quality of the Upham Brook Watershed.” The decision context in this case is necessarily broad. The second step in the process is to establish a set of objectives that further defines what is meant by the overall objective.

Each member of the interdisciplinary group identified and wrote down on post-it notes 10–15 action verbs and nouns that define objectives for improving the quality of the watershed. Similar objectives were grouped together to form an affinity diagram and to determine the objectives of the group (Fig. 1). Keeney’s 10 devices from the previous section were used sequentially through the session to assist each individual in generating as broad a set of objectives as possible.

Figure 1. A sample of the initial groups of objectives.

As the interdisciplinary team viewed the objectives that were developed, it noted that some of the objectives were means objectives that lead to the fulfillment of other fundamental objectives [18,19]. An

example is the action to “increase citizen participation in watershed improvement.” Increased participation does not directly improve the quality of the watershed, even though specific activities like cleaning

Figure 2. Value hierarchy for the Upham Brook Watershed MODA (multiple objective decision analysis) model.

up the banks and removing blockages from streams can improve water quality. Such objectives were removed from the value hierarchy but retained for use in identifying decision alternatives later in the process. The fundamental objectives were then organized into a value hierarchy [19].

To do this, the group sorted through the fundamental objectives to remove repetition and then took each group of fundamental objectives in the affinity diagram and determined which higher level objective the group represented. The set of higher level objectives define the overall objective. It should be noted that additional levels can be used in the value hierarchy, but were not needed in our application.

The members of the group were surprised by the level of thinking involved in this process and the frequent challenges to their own mental models as a result of the diverse backgrounds of the other members. The development of the value hierarchy took nine 2-h sessions. The hierarchy went through several stages of evolution as the group defined what they meant by the quality of the watershed. After a revision of the initial hierarchy, the final value hierarchy was formed (Fig. 2). The value hierarchy may be viewed as the interdisciplinary team's definition of watershed quality [1,19].

The hierarchy divides the quality of a watershed into two objectives: maximizing the quality of wildlife habitat and maximizing the quality of human habitat. The wildlife habitat is broken down into five objectives, one for each class of wildlife species that could reside within the Upham Book Watershed's area. The same five lowest level objectives are listed below each species class. The interdisciplinary team believed that the five objectives would have a different importance for each class of species and possibly different single-dimensional value functions. The human habitat is divided into two objectives: maximize residential value and maximize commercial/industrial value. These two objectives are then broken down into four lowest level objectives that were appropriate for both objectives though with differing importance.

CONCLUSIONS

It is evident that people do not generate complete and comprehensive lists of objectives to use in making better decisions. The results from Bond *et al.* [10] suggest that groups of decision makers and stakeholders should be used to generate the broadest and most comprehensive list of objectives possible. However, the results from Bond *et al.* [12] show that we must use caution in designing the group process. We do not wish objectives generated by other group members to anchor their fellow stakeholders. The 10 devices from Keeney [13] and the questions from Leon [7] can be used to assist in stretching the breadth and depth of the thought process, but group members should be asked to generate objectives independently at first. Further, a second phase asking for additional information should be employed before any group interaction is allowed. In the second phase, stakeholders should be told to generate at least as many new objectives as in the first phase. Category cues can also be employed based on objectives generated by the whole group in the first phase and on relevant vision, policy, or strategy literature. Finally, after two phases of objective generation, the group can work together to remove redundancy and to determine a final list. Furthermore, Leon [7] shows conclusively that the stakeholders should be asked to think about values and objectives throughout the process rather than being anchored to specific alternatives.

DEFINITION AND EXAMPLES OF CONTINUOUS-TIME MARKOV CHAINS

EVIN UZUN

Department of Statistics and
Operations Research,
University of North Carolina,
Chapel Hill, North Carolina

DEFINITIONS

Consider a continuous-time stochastic process $\{X(t), t \geq 0\}$ with a countable state space S . Such a process is said to satisfy the Markov property if the conditional distribution of the future state at time $t + s$, given the present state at s and all states prior to s , depends only on the present state, that is, for all $i, j \in S$ and $s, t \geq 0$,

$$\begin{aligned} P(X(t + s) = j | X(s) = i, X(u) = x(u), 0 \leq u < s) \\ = P(X(t + s) = j | X(s) = i). \end{aligned} \quad (1)$$

Then, $\{X(t), t \geq 0\}$ is called a *continuous-time Markov chain* (CTMC) if it has the Markov property. If, in addition, $P(X(t + s) = j | X(s) = i)$ is independent of s , then the CTMC is said to be *time-homogeneous*. For the rest of this article, we assume that all CTMCs are time-homogeneous. For a time-homogeneous CTMC $\{X(t), t \geq 0\}$, let

$$p_{ij}(t) = P(X(t) = j | X(0) = i), \forall i, j \in S, t \geq 0,$$

be the transition probabilities and

$$P(t) = [p_{ij}(t)], \forall i, j \in S, t \geq 0,$$

be the transition probability matrix (TPM). Next, let $a_i = P(X(0) = i)$ for all $i \in S$, and

$$\mathbf{a} = [a_i], i \in S,$$

be a row vector representing the initial distribution. A CTMC is completely described by

its initial distribution $\mathbf{a}$ and the TPMs $P(t)$ for each $t \geq 0$, see Theorem 6.2 in Ref. 1.

From the Markov property, it follows that the amount of time a CTMC spends in a state i before making a transition into a different state is exponentially distributed with some rate v_i such that $0 \leq v_i \leq \infty$. A state i for which $v_i = \infty$ is called an *instantaneous state* since when entered it is instantaneously left. (If $v_i = 0$, the state i is called an *absorbing state* since when entered it is never left.) A CTMC with such states is called a *nonregular CTMC*. (An example for a nonregular CTMC is the one having $p_{i,i+1} = 1$ and $v_i = i^2$.) A CTMC is said to be regular if the number of transitions at any finite length of time is finite with probability 1. For the rest of this article, we assume that all CTMCs are regular. Then, we can alternatively define a CTMC as follows (A CTMC, defined as below, has the Markov property and is time-homogeneous; see Theorem 6.1 in Ref. 1):

Definition 1. The stochastic process $\{X(t), t \geq 0\}$ is called a *CTMC* if it has a countable state-space S , and the sequence $\{X_0, (X_n, Y_n), n \geq 1\}$ satisfies

$$\begin{aligned} P(X_{n+1} = j, Y_{n+1} > y | X_n = i, Y_n, X_{n-1}, \\ Y_{n-1}, \dots, X_1, Y_1, X_0) \\ = P(X_1 = j, Y_1 > y | X_0 = i) \\ = p_{ij} e^{-v_i y}, i, j \in S, n \geq 0, \end{aligned} \quad (2)$$

where $X_n = i$ denotes that the process is at state i after the n th jump and Y_n is the amount of time spent at state i (which is exponentially distributed with rate v_i), and $P = [p_{ij}]_{i,j \in S}$ is a stochastic matrix with $p_{ii} = 0$ and $0 \leq v_i < \infty$ for all $i \in S$.

Condition (2) implies that Y_1 is exponentially distributed with rate v_i given $X_0 = i$ independent of the history of the process. Moreover, independent of the history of the process upto time t and the time spent at state i , when

the process leaves state i , it will next enter state j with some probability $p_{i,j}$ such that $\sum_{i \in S} p_{i,j} = 1$ and $p_{i,i} = 0$.

Condition (2) also implies that $\{X_n, n \geq 0\}$ is a discrete-time Markov chain (DTMC) on state space S with TPM P . This DTMC is called the *embedded DTMC* corresponding to the CTMC. Hence, Definition 1 tells us that a CTMC is a stochastic process that moves from state to state in accordance with a DTMC and the amount of time it spends in each state before proceeding to another is exponentially distributed.

In Definition 1, P and $v_i, i \in S$, completely characterize a CTMC. (This follows from the time-homogeneity and regularity assumptions; see Ref. 2.) Next, we define a matrix which is sufficient to characterize a CTMC. Let $q_{i,j}$ be defined by $q_{i,j} = v_i p_{i,j}$ for all $i \neq j$. Since v_i is the rate at which the process leaves state i and $p_{i,j}$ is the probability that it then goes to state j , it follows that $q_{i,j}$ is the rate that the process makes a transition into state j when in state i . Hence, $q_{i,j}$ is called the *transition rate* from i to j . The (infinitesimal) generator matrix of a CTMC is defined as

$$Q = [q_{i,j}], i, j \in S,$$

where $q_{i,i} = -\sum_{k \in S, k \neq i} q_{i,k}, i \in S$. Note that the row sums of Q are zero. Moreover, given the generator matrix Q , we can derive P as follows: Let

$$q_i = \sum_{k \in S, k \neq i} q_{i,k} = -q_{i,i}, i \in S.$$

Note that q_i is the rate that the process jumps out of state i . If $q_i = 0$, then state i is an absorbing state, so we define $p_{i,i} = 1$, denoting that the process will stay in state i with probability 1. If $q_i > 0$, we define

$$p_{i,j} = q_{i,j}/q_i, \forall i, j \in S, j \neq i.$$

Note that $v_i = q_i$ for all $i \in S$. Hence, using Q , we generate P and v_i , for all $i \in S$, which implies that a CTMC is characterized by Q .

Finally, the behavior of a CTMC can be visualized using transition rate diagrams. A rate diagram is a directed graph with a vertex for each state $i \in S$, and an edge from i to j if $q_{i,j} > 0$. In the next section, we will see examples of continuous-time Markov chains, and illustrate some of them with transition rate diagrams.

EXAMPLES

Example 1 [Poisson Process]. Consider a Poisson process with rate λ . First of all, the state space is $\{0, 1, 2, \dots\}$, so this stochastic process has a countable state space. Furthermore, the amount of time this process stays at any state is exponentially distributed with rate λ , and the Markov's property defined in Equation (1) holds due to the memoryless property of the exponential distribution. Hence, the Poisson process is a CTMC with $q_i = q_{i,i+1} = \lambda$ and $p_{i,i+1} = 1$. We can write its generator matrix as follows:

$$Q = \begin{bmatrix} -\lambda & \lambda & 0 & 0 & \dots & 0 \\ 0 & -\lambda & \lambda & 0 & \dots & 0 \\ 0 & 0 & -\lambda & \lambda & \dots & 0 \\ \vdots & & & \ddots & & \end{bmatrix}$$

The transition rate diagram for a Poisson process is given in Fig. 1.

Example 2 [Birth and Death Process]. Consider a CTMC with a state space $\{0, 1, 2, \dots\}$ such that the process at state i can only go to either state $i + 1$ or state $i - 1$. Such a process is called a *birth and death* process. We can think of the state of a birth and death process as the size of a population, with the state increasing by one whenever a birth occurs, and the state decreasing by one whenever a death occurs. Let

$$q_{i,i+1} = \lambda_i \text{ and } q_{i,i-1} = \mu_i.$$

Figure 1. Transition rate diagram for a Poisson process.

Figure 2. Transition rate diagram for a birth and death process.

Then, $\{\lambda_i, i \geq 0\}$ are called the *birth rates* and $\{\mu_i, i \geq 1\}$ are called the *death rates*. Therefore, in a birth and death process with i people in the system, the time until the next birth and death are exponentially distributed with rates λ_i and μ_i , respectively. We can write the generator matrix as follows:

$$Q = \begin{bmatrix} -\lambda_0 & \lambda_0 & 0 & 0 & 0 & \cdots & 0 \\ \mu_1 & -\lambda_1 - \mu_1 & \lambda_1 & 0 & 0 & \cdots & 0 \\ 0 & \mu_2 & -\lambda_2 - \mu_2 & \lambda_2 & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & \end{bmatrix}$$

Moreover, we have $q_i = \lambda_i + \mu_i$, and hence

$$\begin{aligned} p_{i,i+1} &= \frac{\lambda_i}{\lambda_i + \mu_i} \text{ and } p_{i,i-1} = \frac{\mu_i}{\lambda_i + \mu_i} \\ &= 1 - p_{i,i+1}. \end{aligned}$$

Furthermore, if $\mu_i = 0$ for all $i \geq 0$, the process is called a *pure birth* process. For instance, the Poisson process in Example 1 is a pure birth process. Similarly, if $\lambda_i = 0$ for all $i \geq 0$, the process is called a *pure death* process.

The transition rate diagram for a birth and death process is illustrated in Fig. 2.

Example 3 [M/M/1 queue]. Consider a system where customers that need a particular service arrive in accordance with a Poisson process with rate λ . The service is provided by a single server and service times are exponentially distributed with a mean of $1/\mu$. This system is called an *M/M/1 queueing system* and the process denoting the number of customers in the queue is a birth and death process with a birth rate λ for all $i \geq 0$ and a death rate μ for all $i \geq 1$. We can write the generator matrix as follows:

$$Q = \begin{bmatrix} -\lambda & \lambda & 0 & 0 & 0 & \cdots & 0 \\ \mu & -\lambda - \mu & \lambda & 0 & 0 & \cdots & 0 \\ 0 & \mu & -\lambda - \mu & \lambda & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & \end{bmatrix}$$

Example 4 [M/M/1 Queue with Reneging]. Consider the M/M/1 queueing system in Example 3. Assume, in addition, that a customer leaves the system if she waits longer than her maximum waiting time in the queue, which is an exponentially distributed random variable with a mean of $1/\gamma$. Then, the process denoting the number of customers in the queue is a birth and death process with a birth rate λ for all $i \geq 0$ and a death rate $\mu + i\gamma$ for all $i \geq 1$. We can write the generator matrix as follows:

$$Q = \begin{bmatrix} -\lambda & \lambda & 0 & 0 & 0 & \cdots & 0 \\ \mu + \gamma & -\lambda - \mu - \gamma & \lambda & 0 & 0 & \cdots & 0 \\ 0 & \mu + 2\gamma & -\lambda - \mu - 2\gamma & \lambda & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & \end{bmatrix}$$

Example 5 [An Epidemic Model].

This example is from Ref. 3, and it considers a population of $m \geq 1$ people with one infected person and $m - 1$ susceptible people at time zero. In any time interval h , any given infected person infects any susceptible person with probability $h\alpha + o(h)$, and once infected, a person stays infected forever. Then, the process denoting the number of infected people in the system is a pure birth process with state space $S = \{1, \dots, m\}$ and birth rate $\lambda_i = i(m - i)\alpha$ for all $i \in S$. For example, for $m = 5$, we can write the generator matrix as follows:

$$Q = \begin{bmatrix} -4\alpha & 4\alpha & 0 & 0 & 0 \\ 0 & -6\alpha & 6\alpha & 0 & 0 \\ 0 & 0 & -6\alpha & 6\alpha & 0 \\ 0 & 0 & 0 & -4\alpha & 4\alpha \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Example 6 [An Epidemic Model with Recovery]. Consider the epidemic model in Example 5. Assume, in addition, that infected people recover from the infection after some time, but after the recovery, they can be infected again. The recovery

time for each infected person is exponentially distributed with a mean of $1/\mu$. Then, the process denoting the number of infected people in the system is a birth and death process with state space $S = \{0, 1, \dots, m\}$. Considering the transition rates, for all $i \in S$, the birth and death rates are given by $\lambda_i = i(m-i)\alpha$ and $\mu_i = i\mu$, respectively. For example, for $m = 5$, we can write the generator matrix as follows:

$Q =$

$$\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ \mu & -4\alpha - \mu & 4\alpha & 0 & 0 & 0 \\ 0 & 2\mu & -6\alpha - 2\mu & 6\alpha & 0 & 0 \\ 0 & 0 & 3\mu & -6\alpha - 3\mu & 6\alpha & 0 \\ 0 & 0 & 0 & 4\mu & -4\alpha - 4\mu & 4\alpha \\ 0 & 0 & 0 & 0 & 5\mu & -5\mu \end{bmatrix}$$

DEFINITION AND EXAMPLES OF DTMCs

NATARAJAN GAUTAM
Department of Industrial and Systems
Engineering, Texas A&M University,
College Station, Texas

A stochastic process describes the state of a system and its random evolution over time. Broadly speaking, stochastic processes are of four types depending on whether the system is observed continuously or at discrete time points, and whether the observations or states are discrete quantities or continuous, as follows:

1. *Discrete State and Discrete Observation.* The number of cereal boxes on a grocery store shelf observed at the beginning of a day.
2. *Discrete State and Continuous Observation.* The number of e-mails in someone's *InBox* observed at all times.
3. *Continuous State and Discrete Observation.* The amount of water in a reservoir observed immediately after a rain shower.
4. *Continuous State and Continuous Observation.* The temperature inside a car observed all the time.

A discrete-time Markov chain (DTMC) is a special type of stochastic process belonging to the first category; that is, system states are discrete and system is observed at discrete times. All DTMCs are discrete state and discrete observation stochastic processes but for a stochastic process to be a DTMC, some other conditions need to be satisfied which are provided in the next section. However, it is crucial to point out that the observations do not have to be periodic (although in most cases they would be), such as every day or every hour. It is also critical to realize that the notion of "time" is not rigid; for example, the observations can be done over

space (but that is certainly atypical). In summary, DTMCs can be applied in fairly general settings to situations commonly found in real life. They have gained significant attention in the queueing [1] and inventory [2] literature, and have been used extensively in the analysis of production systems, computer-communication systems, transportation systems, biological systems, and so on.

We first describe the definition and notations used in modeling a system as a DTMC. This is the focus of the section titled "Definition and Notation." Then, in the section titled "Modeling a System as a DTMC," we provide a methodical technique to model a given system using a DTMC. Finally, in the section titled "Examples," we describe several examples to illustrate the modeling framework as well as to motivate the wide variety of applications where DTMCs are used. In addition, there are several texts [3,4] and websites (<http://www.sosmath.com/matrix/markov/markov.html>) that provide additional examples that would enhance the understanding of concepts included in this article.

DEFINITION AND NOTATION

Consider a system that is randomly evolving in time. Let X_n be the state of the system at the n th observation. In essence, X_n describes the system based on the n th observation. For example, X_n could be (i) the status of a machine (up or down) at the beginning of the n th hour; (ii) the number of repairs left to be completed in a shop at the end of the n th day; (iii) the cell phone company a person is with when he/she received his/her n th phone call; (iv) the number of boys and the number of girls in a classroom at the beginning of the n th class period; (iv) the number of gas stations at the n th exit on a highway.

It is crucial to understand that although all the above examples are discrete states and discrete observations, it is not necessary

that the stochastic process $\{X_0, X_1, X_2, \dots\}$ is a DTMC. For that, some additional properties are necessary. However, notice from the examples that the states can be one-dimensional or multidimensional, they can take finite or infinite values, they could be over time or space, they do not have to be equally spaced (periodic), and they do not have to be numerical values. We define the *state space* S as the set of all possible values of X_n for all n . In the previous paragraph, in example (i) we have $S = \{Up, Down\}$, in example (ii) we have $S = \{0, 1, 2, \dots\}$, and in example (iv) we have $S = \{(0, 0), (0, 1), (1, 0), (1, 1), (0, 2), (2, 0), \dots\}$. In summary, we require X_n and S to be discrete valued (or also called *countable*).

The next question to ask is when can a stochastic process $\{X_0, X_1, X_2, \dots\}$ be called a DTMC? A stochastic process $\{X_0, X_1, X_2, \dots\}$, which we henceforth denote as $\{X_n, n \geq 0\}$, is called a DTMC if it satisfies the *Markov property*. In words, Markov property states that if the current state of the system is known, the future states are independent of the past. In other words, to predict (probabilistically) the states in the future, all one needs to know is the present state and nothing from the past. For example, if X_n denotes the amount of inventory of a product at the beginning of the n th day (say today), then it is conceivable that to predict the inventory at the beginning of the next day and the day after, all one would need is today's inventory. Yesterday's inventory or how you got today's inventory is not necessary.

Mathematically, Markov property is defined as

$$\begin{aligned} P\{X_{n+1} = j \mid X_n = i, X_{n-1} = i_{n-1}, \\ X_{n-2} = i_{n-2}, \dots, X_0 = i_0\} \\ = P\{X_{n+1} = j \mid X_n = i\}. \end{aligned}$$

In other words, once X_n is known, we can predict (probabilistically) $X_{n+1}, X_{n+2}, \dots$ without needing to know $X_{n-1}, X_{n-2}, \dots$. In summary, a stochastic process $\{X_n, n \geq 0\}$ defined on a countable state space S is called a DTMC if it satisfies the Markov property. This is the technical definition of a DTMC. Now that we have defined a DTMC, in the next

section we explain how a system can be modeled as a DTMC so that the system can be analyzed.

MODELING A SYSTEM AS A DTMC

Before presenting a systematic approach to modeling a system as a DTMC, we provide some more assumptions and notation. Besides the Markov property, there is another property that needs to be satisfied in order to be able to effectively analyze a DTMC. A DTMC is called *time homogeneous* if the probability of transition from a state to another state does not vary with time. In other words, for a DTMC with state space S to be time homogeneous, for every $i \in S$ and $j \in S$,

$$P\{X_{n+1} = j \mid X_n = i\} = P\{X_1 = j \mid X_0 = i\}.$$

We denote the above expression as p_{ij} , the one-step transition probability of going from state i to j . Therefore, for a time-homogeneous DTMC, for $i \in S$ and $j \in S$,

$$p_{ij} = P\{X_{n+1} = j \mid X_n = i\}.$$

Notice that p_{ij} is not a function of n which is essentially because the DTMC is time homogeneous.

Using the transition probabilities p_{ij} for every $i \in S$ and $j \in S$, we can build a square matrix $P = [p_{ij}]$. The matrix P is called *transition probability matrix*. The rows of the matrix correspond to the given current state, while the columns correspond to the next state. The sum of the elements of each row adds to 1 because given that the DTMC is in state i (for some $i \in S$), the next state ought to be one of the states in S ; hence, for every $i \in S$,

$$\sum_{j \in S} p_{ij} = 1.$$

Oftentimes, a transition diagram is used to represent the transition probabilities, as opposed to the matrix P . A transition diagram is a directed graph with nodes corresponding to the states (thereby the set of nodes is indeed S), arcs corresponding to possible one-step transitions, and arc values being

Figure 1. Transition Diagram for Jill's Switching Patterns

transition probabilities. To draw a transition diagram, for every $i \in S$ and $j \in S$, draw an arc from node i to node j if $p_{ij} > 0$. Now we illustrate an example of X_n , S , the transition probability matrix P , and transition diagram.

Consider three long-distance telephone companies A , B , and C . Every time a sale is announced, users switch from one company to another. Let X_n denote the long-distance company with which a particular user named Jill is just before the n th sale announcement. We have $S = \{A, B, C\}$. On the basis of the customers' switching in the past, it is estimated that Jill's switching patterns follow the following transition probability matrix:

$$P = \begin{matrix} & \begin{matrix} A & B & C \end{matrix} \\ \begin{matrix} A \\ B \\ C \end{matrix} & \begin{bmatrix} 0.3 & 0.4 & 0.3 \\ 0.5 & 0.3 & 0.2 \\ 0.4 & 0.1 & 0.5 \end{bmatrix} \end{matrix}.$$

For example, if Jill is with B before a sale is announced, she would switch to A with probability 0.5 and C with probability 0.2 or stay with B with probability 0.3, as evident from the second row in P . Now, converting the above P matrix into a transition diagram, we get the picture as shown in Fig. 1.

Having described all the definitions, notations, and requirements, we are now ready to model a system as a DTMC. Five steps are involved in systematically modeling a system as a DTMC: (i) define X_n ; (ii) write down S ; (iii) verify that the Markov property is satisfied; (iv) verify that the DTMC is time homogeneous; and (v) obtain P or draw the transition diagram.

Next, we present some examples where systems are modeled as DTMCs using the five steps described above. Note that although modeling a system as a DTMC is considered an art, the key scientific aspect is that X_n must be chosen carefully so that S is as small as possible and steps (iii)–(v) can be performed. If not, one must consider revising X_n . In particular, one of the most important steps in modeling is to choose X_n so that Markov property is satisfied. One approach is to define X_n in such a way that it carries all the past information needed to forecast the future states, or that the future state could be written in terms of only the present state and some other factors that are independent of the past and present states. We illustrate this in some of the examples in the next section.

EXAMPLES

In the examples that follow, the objective is to model the system described as a DTMC by stating X_n and S as well as obtaining P . The order of states in the rows and columns of the P matrices is identical to those in the order of the corresponding S .

Example 1. A company uses two forecasting tools for making demand predictions. Tool i is effective with probability p_i (for $i = 1, 2$). If the n th prediction uses tool i and it is observed to be effective, then the $(n + 1)$ th prediction is also done using the same tool; if it is observed to be ineffective, then the $(n + 1)$ th prediction is made using the other tool. This is sometimes known as “play the winner rule.”

To model this system as a DTMC, we let X_n to be the tool used for the n th prediction. The state space $S = \{1, 2\}$. It can be verified that Markov property is satisfied because the tool used for the $n + 1$ th prediction depends on only what was used for the n th prediction and the outcome of the n th prediction and not the history. Further, p_i for $i = 1, 2$ remains constant over time; hence, the DTMC is time homogeneous. Clearly, from the description,

$$P = \begin{bmatrix} p_1 & 1 - p_1 \\ 1 - p_2 & p_2 \end{bmatrix}.$$

Example 2. Probe vehicles are sent through two similar routes from source A to destination B to determine the travel times. If a route was congested when a probe vehicle is sent, then it will be congested with probability q when the next probe vehicle needs to be sent. Likewise, if a route was not congested when a probe vehicle is sent, it will not be congested with probability p when the next probe vehicle is sent. The routes behave independent of each other and since they are similar we assume that p and q do not vary between the routes.

Let X_n be the number of uncongested routes when the n th set of probe vehicles are sent. The state space $S = \{0, 1, 2\}$. It can be verified that Markov property is satisfied because the congestion states of each route depends only on whether they were congested during the previous probe and not the history. Further, p and q remain constant over time; hence, the DTMC is time homogeneous. From the description, it is possible to show that

$$P = \begin{bmatrix} q^2 & 2q(1-q) & (1-q)^2 \\ q(1-p) & pq + (1-p)(1-q) & p(1-q) \\ (1-p)^2 & 2p(1-p) & p^2 \end{bmatrix}.$$

It may be worthwhile to describe some of the above p_{ij} values. In particular, $p_{02} = (1 - q)^2$ since the probability of going from both routes being congested to no route congested is if both congested routes become uncongested, each happening with probability $1 - q$. Likewise $p_{10} = q(1 - p)$ because the probability that the congested route remains congested is q and the probability that the uncongested route becomes congested is $1 - p$. In a simi-

lar manner, all the p_{ij} values can be obtained using a similar logic.

Example 3. Consider the following weather forecasting model: if today is sunny and it is the n th day of the current sunny spell, then it will be sunny tomorrow with probability p_n regardless of what happened before the current sunny spell started. Likewise, if today is rainy and it is the n th day of the current rainy spell, then it will be rainy tomorrow with probability q_n regardless of what happened before the current rainy spell started.

Oftentimes, one is tempted to say that the state of the system is the type of day (sunny or rainy). However, one of the concerns is that Markov property would not be satisfied since to predict the next state one needs to know the history to figure out how long the spell has been. Therefore, one needs to carry the spell information too in the state. In this light, let X_n be a two-dimensional state denoting the type of day on the n th day and how many days the current spell has lasted. Letting s and r to denote rainy and sunny respectively, the state space S is $S = \{(s, 1), (r, 1), (s, 2), (r, 2), (s, 3), (r, 3), \dots\}$. It can easily be verified that Markov property is satisfied. The DTMC is time homogeneous, although one must not mistake n in p_n or q_n to be the n in X_n . Consider that the system is in state (s, i) during a day. Then, from the description, on day $n + 1$ the system would be in state $(s, i + 1)$ with probability p_i if it does not rain and $(r, 1)$ with probability $1 - p_i$ if it does rain. A similar argument can be made for (r, i) . Therefore, the P matrix in the order the states are represented in S is

[illegible]

Example 4. Many biological processes especially at the cellular level are a result of polymerization and depolymerization of organic compounds. A polymer in a cell is made up of N monomers that are attached back to back with one end of the chain anchored to the cell and the other end grows or shrinks. For example, a polymer $M_0-M-M-M$ is made of four monomers and M_0 indicates it is anchored. In each time unit with probability p , a new monomer joins the growing end, and with probability q the nonanchored end monomer leaves the polymer. For example, the $M_0-M-M-M$ chain in the next time unit becomes $M_0-M-M-M-M$

$$P = \begin{bmatrix} 1-p & p & 0 & 0 & 0 & \dots \\ q & 1-p-q & p & 0 & 0 & \dots \\ 0 & q & 1-p-q & p & 0 & \dots \\ 0 & 0 & q & 1-p-q & p & \dots \\ 0 & 0 & 0 & q & 1-p-q & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

Example 5. A machine produces two items per day. The probability that an item is nondefective is p . Successive items are independent. Defective items are thrown away instantly. The demand is one item per day which occurs at the end of a day. Any demand that cannot be satisfied immediately is lost.

Let X_n be the number of items in storage at the beginning of the n th day (before production and demand of that day). Since demand takes place after production on a given day, we have, if $X_n > 0$,

$$X_{n+1} = \begin{cases} X_n + 1 & \text{w.p. } p^2 \\ X_n & \text{w.p. } 2p(1-p) \\ X_n - 1 & \text{w.p. } (1-p)^2 \end{cases}$$

and, if $X_n = 0$,

$$X_{n+1} = \begin{cases} X_n + 1 & \text{w.p. } p^2 \\ X_n & \text{w.p. } 1-p^2 \end{cases}$$

Since X_{n+1} depends only on X_n , this is a DTMC with state space $S = \{0, 1, 2, \dots\}$. The transition probabilities p_{ij} for all $i \geq 0$ and

with probability p , M_0-M-M with probability q , and stays as $M_0-M-M-M$ with probability $1-p-q$.

We consider a single polymer and let X_n denote the length of the polymer (in terms of number of monomers) at the beginning of the n th time unit. Therefore, the state space is $S = \{1, 2, 3, 4, \dots\}$. Since one side is anchored, we assume that the last monomer would never break away. Verify that Markov property is satisfied and $\{X_n, n \geq 0\}$ is time homogeneous. The P matrix in the order the states are represented in S is

$$P = \begin{bmatrix} 0 & 0 & 0 & 0 & \dots \\ 0 & 0 & 0 & 0 & \dots \\ p & 0 & 0 & 0 & \dots \\ 1-p-q & p & 0 & 0 & \dots \\ q & 1-p-q & p & 0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

$j \geq 0$ are given by

$$p_{ij} = \begin{cases} p^2, & \text{if } j = i + 1, \\ 2p(1-p), & \text{if } j = i \text{ and } i > 0, \\ 1-p^2, & \text{if } j = i = 0, \\ (1-p)^2, & \text{if } j = i - 1, \\ 0, & \text{otherwise.} \end{cases}$$

Example 6. Consider a time division multiplexer from which packets are transmitted at times 0, 1, 2, and so on. Packets arriving between time n and $n+1$ have to wait until time $n+1$ is transmitted. However, at most, one packet can be transmitted at a time. Let Y_n be the number of packets that arrive during time n to $n+1$. Assume that $a_i = P\{Y_n = i\}$ and that there is infinite room in the waiting space.

Let X_n be the number of packets awaiting transmission just before time n . Clearly, we have the state space $S = \{0, 1, 2, \dots\}$. Define the transition probabilities p_{ij} as (for $i > 0$)

$$\begin{aligned} p_{ij} &= P\{X_{n+1} = j \mid X_n = i\} \\ &= a_{j-i+1}. \end{aligned}$$

Figure 2. Transition Diagram for Manufacturing System in Example 7

Similarly,

$$p_{0j} = P\{X_{n+1} = j \mid X_n = 0\} = P\{Y_n = j\} = a_j.$$

Verify that Markov property is satisfied and $\{X_n, n \geq 0\}$ is time homogeneous. Therefore, the transition probability matrix $P = [p_{ij}]$ is

$$P = \begin{bmatrix} a_0 & a_1 & a_2 & a_3 & \dots \\ a_0 & a_1 & a_2 & a_3 & \dots \\ & a_0 & a_1 & a_2 & \dots \\ & & a_0 & a_1 & \dots \\ & & & a_0 & \dots \end{bmatrix}.$$

Example 7. Consider a manufacturing system of two identical machines that are in working condition; one is in use and the other is in standby. The probability that a machine that is in use fails during an hour is p (assume that a machine in standby mode does not fail). The system is observed once every hour. It takes just a little less than 3 h to repair a failed machine. Only one machine can be repaired at a time and repairs are according to first-come first-serve basis.

Let X_n be the number of machines in working condition at the beginning of time unit n . Let Y_n be the number of time units of repair completed at the beginning of time unit n . Notice that X_n and Y_n are chosen such that Markov property is satisfied and $\{(X_n, Y_n), n \geq 0\}$ is time homogeneous. Therefore, $\{(X_n, Y_n), n \geq 0\}$ is a DTMC with the transition diagram shown in Fig. 2.

DEFINITION AND EXAMPLES OF RENEWAL PROCESSES

LIQIANG LIU
EURANDOM, Eindhoven
University of Technology,
Eindhoven, Netherlands

This article introduces a class of stochastic processes called *renewal processes*, occasionally referred to as *recurrent processes*, which play several important roles in the grand scheme of stochastic processes.

First, they help us relax distributional assumptions in Markov chains, namely, the geometric distributions for the DTMCs (discrete-time Markov chains), and the exponential distributions for the CTMCs (continuous-time Markov chain). Renewal processes provide us with important tools (see **Limit Theorems for Renewal Processes**) to deal with general distributions.

Second, renewal processes provide a unifying theoretical framework (renewal theory) for studying the limiting behavior of specialized stochastic processes. For example, we shall see that renewal processes appear as embedded processes in the DTMCs and the CTMCs, and thus convergence results about these processes can be obtained within the framework of renewal theory.

Third, renewal processes lead to important generalizations such as semi-Markov processes (see **Semi-Markov Processes**) and regenerative processes (see **Markov Regenerative Processes**). With the capacity to handle general cost and reward structures, renewal processes and their generalizations are effective and prevailing stochastic models in operations research and management science.

DEFINITIONS

Consider a certain event repetitively occurring at time $S_1, S_2, \dots$. Assume

$$0 \leq S_1 \leq S_2 \leq \dots$$

Thus S_n is the time of the n th occurrence of the event. Define

$$X_n = S_{n+1} - S_n, \quad n \geq 1.$$

Thus $X_1, X_2, \dots$ is a sequence of waiting times between two successive occurrences of the event. Let $S_0 = 0$ by convention. Next, we define

$$N(t) = \sup\{n \geq 0 : S_n \leq t\}, \quad t \geq 0.$$

Thus the process $\{N(t), t \geq 0\}$ counts the number of occurrences of the event up to time t . A typical sample path of this process is shown in Fig. 1. The process is a continuous-time process with piecewise constant right-continuous sample paths. With these notations we are ready to define a renewal process.

Definition 1 [Renewal sequence, renewal process]. The sequence $S_1, S_2, \dots$ is called the *renewal sequence* and the process $\{N(t), t \geq 0\}$ is called the *renewal process* if

1. $S_1, X_1, X_2, \dots$ are mutually independent nonnegative random variables,
2. $X_1, X_2, \dots$ have a common distribution F and $F(0) < 1$.

Definition 2 [Pure and delayed renewal process]. A renewal process is pure if S_1 is a random variable with a distribution $G = F$, and is delayed if $G \neq F$. A pure renewal process is also known as an *ordinary renewal process*.

Definition 3 [Recurrent and transient renewal process]. A renewal process is recurrent if F is a proper distribution, or transient if F is defective. Here F is proper means that $F(\infty) = \lim_{t \rightarrow \infty} F(t) = 1$. If $F(\infty) < 1$, the distribution is defective. It means that there is a positive probability that the random variable is unbounded. This implies that almost surely $X_n = \infty$ for

Figure 1. Sample path of a counting process.

some $n = K$, so that the repetition eventually terminates after K times. Recurrent renewal process is also known as *persistent renewal process*. Transient renewal process is also known as *terminating renewal process*.

The distribution F is also known as *inter-renewal, waiting, holding or recurrence-time distribution*. We assume $F(0) < 1$ to exclude the trivial case, $S_n - S_1 = 0$ for all $n > 1$ with probability 1. Note that allowing $X_n = 0$ with a positive probability implies that the event may occur multiple and almost surely finite times simultaneously. Some authors [1–3] define renewal process to be the process $\{S_n, n \geq 1\}$. This is a mathematically equivalent definition in a sense that

$$N(t) \leq n \text{ if and only if } S_{n+1} > t,$$

$$N(t) \geq n \text{ if and only if } S_n \leq t.$$

In this case $\{N(t), t \geq 0\}$ and $\{S_n, n \geq 1\}$ are called it renewal counting process and *renewal point process*, respectively, for clearness [4].

EXAMPLES

Example 1 [Coin tossing]. Consider tossing a coin in a row and the event: the outcome is head. Suppose for each toss, the probability of getting a head is p . Let S_n be the trial at which the n th head is obtained and the next head is obtained after X_n tosses. Then the sequence $S_1, S_2, \dots$ is a renewal sequence with recurrence time of geometric distribution,

$$\begin{aligned} \mathbb{P}\{S_1 = k\} &= \mathbb{P}\{X_n = k\} = (1-p)^{k-1}p, \\ k, n &= 1, 2, \dots \end{aligned}$$

Example 2 [Poisson process]. A Poisson process with mean arrival rate λ is a renewal process with F being the exponential distribution with mean $1/\lambda$. Thus, a renewal process can be seen as a direct generalization of the Poisson process with respect to a relaxation of the exponential assumption in the waiting-time distribution.

Example 3 [Renewal processes in Markov chains]. Let $\{Y(t), t \geq 0\}$ be a CTMC on $\{1, 2, \dots\}$. Let $S_n, n \geq 1$ be the time of the n th occurrence of the event: the state transits from some $i > 0$ into 0. Let $N(t)$ count the number of such transitions up to time t . Since $X_n = S_{n+1} - S_n$ is the time between two successive transitions into state 0, the Markov property of the CTMC implies that $X_1, X_2, \dots$ is a sequence of iid (independent and identically distributed) positive random variables. Hence $\{N(t), t \geq 0\}$ is a renewal process. If $Y(0) = 0$ with probability 1, then this renewal process is pure. Similarly, we can also identify renewal processes in a DTMC.

Example 4 [Machine maintenance]. Suppose a manufacturing process requires continuous use of a machine. Suppose we follow the age-replacement policy: replace the machine in use when it fails or when it reaches an age of T years. This policy is useful in reducing the number of on-job failures, which tend to be more costly. If we schedule our replacement more frequently (smaller T),

then there would be less on-job failures. Let L be the lifetime of a new machine. Assume replacement of the machine is completed instantaneously. Let $S_n, n \geq 1$ be the time of the n th replacement. This is a renewal sequence since $X_1, X_2, \dots$ are iid copies of the random variable $X = \min(T, L)$.

One may also consider a subsequence such as the epochs when a failed machine is replaced. Let S_{I_n} be the time of the n th failure. Then $I_1, I_2, \dots$ is a renewal sequence in the “Coin tossing” example above (Example 1), with $p = \mathbb{P}\{T \geq L\}$. By Definition 1, it is easy to check that a subsequence of a renewal sequence is also renewal if the subindex sequence is renewal. Thus the on-job replacement times, $S_{I_1}, S_{I_2}, \dots$ is a renewal sequence. Similarly, the planned replacement times also form a renewal sequence.

The renewal processes illustrated in this example are pure if we begin with a new machine at time 0.

Example 5 [Renewal processes in queueing models]. Consider a $G/G/1$ queue. We can easily identify the arrival epochs $S_1, S_2, \dots$ form a renewal sequence, since by definition (see *The G/G/1 Queue*) the interarrival times in a $G/G/1$ queue are nonnegative iid random variables. Hence $\{N(t), t \geq 0\}$, which counts the number of arrivals up to time t is a renewal process. We say the arrival process is renewal. Here, we see an example of renewal process being an explicit assumption in the queueing model.

Next, let us consider event a : a customer arrives at an empty queue, which occurs chronologically at time $A_1, A_2, \dots$. Intuitively, after each occurrence of such an event, the queueing system restarts from scratch in the sense that the evolution of the queue is a replica of its evolution after A_1 . Thus $A_1, A_2, \dots$ is a renewal sequence.

Last, let us consider another event d : the queue becomes empty after a customer departs, and check whether the epochs form a renewal sequence. Let D_n be the n th epoch when event d occurs. Clearly, event a and event d occur alternatively. Suppose the system is empty at time 0. Then we get a sequence $A_1, D_1, A_2, D_2, \dots$ if we

order the occurrences of both events. Define $B_n = D_n - A_n$ and $I_n = A_{n+1} - D_n$, $n \geq 1$. The random variable B_n is the n th busy period and I_n is the n th idle period (we do not count the period from 0 to A_1 as the first idle period). Since the system “starts from scratch” after each occurrence of event a , the sequence $B_1, B_2, \dots$, the sequence $I_1, I_2, \dots$, and the sequence $(B_1, I_1), (B_2, I_2), \dots$ are all iid. (The last bivariate random variable sequence is called it alternating renewal sequence. See *Alternating Renewal Processes*) However, for $G/G/1$ queue, $D_1, D_2, \dots$ is not necessarily a renewal sequence since $D_{n+1} - D_n = I_n + B_{n+1}$ and I_n may depend on B_n . If the distribution of interarrival time is exponential, then, due to the memoryless property, $B_1, I_1, B_2, I_2, \dots$ is a sequence of mutually independent random variables. Hence for $M/G/1$ queues, $D_1, D_2, \dots$ is a renewal sequence.

REMARKS

The intrinsic property that defines the renewal process is the existence of a sequence of nonnegative iid random variables, that is, the recurrence times. In layman’s terms, the event recurs in a way that no matter when it occurs or what happened before that, the waiting time until the next occurrence is always the same, of course, in a stochastic sense. For this salient feature, renewal process earns its important footing in the study of stochastic processes. The probability law of a stochastic process may be too intricate to analyze completely but the existence of an embedding renewal sequence helps us understand essential features of the process, prove limit theorems, and so on. The study of renewal processes, called *renewal theory*, contributes greatly to the simplification and unification of many theories. For further coverage of this topic, the reader is encouraged to see the excellent monographs by Feller [1] and Cox [2], or a fine expository article by Smith [5].

Lastly, it should be remarked that the definition of renewal process is not restricted to the temporal interpretation of t . For example, S_n can also be thought of as the location of a

set of particles on a line and $N(t)$ counts the number of particles in the segment $[0, t]$.

DEGENERACY AND VARIABLE ENTERING/EXITING RULES

ISTVÁN MAROS
Department of Computing,
Imperial College London,
London, UK

Department of Computer
Science and Systems
Technology, University of
Pannonia, Veszprém,
Hungary

The simplex method (SM) of linear programming (LP) is an iterative algorithm. The feasible set of an LP problem, if not empty, is a convex polyhedron. Assume it is nonempty. Theory has shown that an optimal solution to a problem, if exists, is achieved at a vertex of this set. A vertex of the polyhedron algebraically corresponds to a basic solution. The SM moves from a basic solution (basis) to a neighboring basic solution along a connecting edge such that the objective value in the new vertex is better (not worse) in terms of the objective value. Thus, an iteration of the SM consists of two steps, finding an improving direction and then identifying the neighboring vertex (finding the steplength) in that direction.

If the solution in the neighboring basis is always better then no basis can be repeated and the algorithm terminates in a *finite number of iterations* either at an optimal solution or detects that the solution is unbounded.

Neighboring bases differ from each other in just one column. So, an iteration consists of determining an “incoming” (entering) nonbasic column and an “outgoing” (exiting) basic column.

Finiteness of the SM can be in danger if the steplength of an iteration is zero (nonimproving iteration). This can happen in the presence of degeneracy and can lead to a sequence of nonimproving iterations and a return to the first basis in the sequence. If it happens the sequence is repeated infinitely resulting in cycling and the SM does not terminate.

This situation was early recognized when the proof of finiteness of the SM was constructed. First the proof was completed under the “nondegeneracy assumption,” that is, all bases were assumed nondegenerate. Later, theoretically sound rules [1] were introduced regarding how to choose the entering and exiting variables during iterations such that finiteness is guaranteed.

In the sequel we give a definition of degeneracy and investigate the phenomenon both from theoretical and computational point of views.

PROBLEM STATEMENT, DEFINITIONS

What is degeneracy? How does it come about? How does it cause problems, if at all? How can it disappear? To answer these questions we consider the following general LP problem:

$$\min z = \sum_{j=1}^n c_j x_j$$

subject to

$$L_i \leq \sum_{j=1}^n a_j^i x_j \leq U_i, \quad i = 1, \dots, m$$

(general constraints)

$$\ell_j \leq x_j \leq u_j, \quad j = 1, \dots, n$$

(individual bounds).

After suitable transformations and the introduction of a new variable for each general constraint, we obtain

$$z_i + \sum_{j=1}^n a_j^i x_j = b_i, \quad i = 1, \dots, m, \quad (1)$$

where z_i 's are called *logical variables* while x_j 's are *structural variables*. Equation (1) can be written in matrix form

$$\mathbf{I}z + \mathbf{A}x = \mathbf{b},$$

or after redefining variables and the matrix of constraints

$$\mathbf{Ax} = \mathbf{b}. \quad (2)$$

Individual bounds can be translated such that the finite lower bounds are all zero. In vector form they can be written as $\ell \leq \mathbf{x} \leq \mathbf{u}$. Components of the lower bound vector belonging to free variables are $-\infty$. Details of bringing a general LP to this form can be found in Maros [2].

As matrix $\mathbf{A}$ of Equation (2) is of full row rank, there are m linearly independent columns of $\mathbf{A}$ that form a basis $\mathbf{B}$. Without restriction of generality, it can be assumed that they are the first m columns of $\mathbf{A}$, that is, $\mathbf{A} = [\mathbf{B} \ \mathbf{R}]$, where $\mathbf{R}$ denotes the “remaining” part of the matrix. With this notation the LP problem can be written in a partitioned form

$$\begin{aligned} \min \quad & z = \mathbf{c}_B^T \mathbf{x}_B + \mathbf{c}_R^T \mathbf{x}_R \\ \text{subject to} \quad & \mathbf{B}\mathbf{x}_B + \mathbf{R}\mathbf{x}_R = \mathbf{b} \end{aligned} \quad (3)$$

$$\ell_B \leq \mathbf{x}_B \leq \mathbf{u}_B \quad (4)$$

$$\ell_R \leq \mathbf{x}_R \leq \mathbf{u}_R. \quad (5)$$

Expressing $\mathbf{x}_B$ from Equation (3)

$$\mathbf{x}_B = \mathbf{B}^{-1}(\mathbf{b} - \mathbf{R}\mathbf{x}_R). \quad (6)$$

Definition 1. A basis $\mathbf{B}$ (basic solution $\mathbf{x}_B$) is *feasible* if $\mathbf{x}_B$ satisfies Equations (3)–(5).

Definition 2. A basis (basic solution) is *degenerate* if at least one of the basic variables has a value equal to its lower or upper bound.

An immediate consequence of this definition is that a free basic variable ($-\infty \leq x_{Bi} \leq +\infty$) never causes degeneracy as it has no individual bound, while a fixed basic variable ($\ell_{Bi} = x_{Bi} = u_{Bi}$, e.g., z_i of an equality constraint) always makes the basis degenerate.

Let $\mathcal{D}$ denote the set of basic positions that contribute to the degeneracy of the basis. We can say that the basic solution is nondegenerate if $\mathcal{D} = \emptyset$. Otherwise, it is degenerate. The *degree of degeneracy* is the number of degenerate positions: $|\mathcal{D}|$.

RATIO TEST IN THE SIMPLEX METHOD

If the current basis is not optimal the simplex method chooses a nonbasic variable that violates its optimality condition to enter the basis as it has the potential of improving the objective function. The outgoing (leaving, or exiting) variable must be chosen in such a way that the other basic variables remain feasible after the basis change. This is achieved by the application of the ratio test as described by Dantzig [3] for the standard LP problem (all constraints are equalities, all variables are nonnegative, $x_j \geq 0, \forall j$).

Here, we consider a more general version of the ratio test [2] that takes into account finite lower and/or upper bounds on variables.

As the incoming variable, say x_q , improves the objective function proportionally to its displacement t , the purpose is to move it away from its current nonbasic value (lower or upper bound) as far as possible. This movement is stopped either by a basic variable that would go infeasible or the individual upper bound u_q of x_q itself.

In Equation (6) the values of basic variables are uniquely determined by the values of nonbasic variables. As some nonbasic variables can be at upper bound

$$\mathbf{x}_B = \mathbf{B}^{-1} \left(\mathbf{b} - \sum_{k \in \mathcal{U}} u_k \mathbf{a}_k \right), \quad (7)$$

where $\mathbf{a}_k$ is column k of $\mathbf{A}$ in Equation (2) and $\mathcal{U}$ is the index set of nonbasic variables at upper bound

$$\mathcal{U} = \{k : k \in \mathcal{R}, x_k = u_k\}.$$

Introducing notation

$$\mathbf{b}_U = \mathbf{b} - \sum_{k \in \mathcal{U}} u_k \mathbf{a}_k,$$

Equation (7) can be written as

$$\mathbf{x}_B = \mathbf{B}^{-1} \mathbf{b}_U, \text{ or } \mathbf{B}\mathbf{x}_B = \mathbf{b}_U. \quad (8)$$

If the improving variable changes from x_q to $x_q + t$ with $t > 0$, then basic variables also

change their values to maintain the main equations (Eq. 8)

$$\begin{aligned} \mathbf{B}\mathbf{x}_B(t) + t\mathbf{a}_q &= \mathbf{b}_U, \text{ or} \\ \mathbf{x}_B(t) &= \mathbf{B}^{-1}\mathbf{b}_U - t\mathbf{B}^{-1}\mathbf{a}_q. \end{aligned} \quad (9)$$

Using notations $\alpha_q = \mathbf{B}^{-1}\mathbf{a}_q$, $\beta = \mathbf{B}^{-1}\mathbf{b}_U$, and $\beta(t) = \mathbf{x}_B(t)$, the second equation of Equation (9) becomes

$$\beta(t) = \beta - t\alpha_q. \quad (10)$$

The i th component of Equation (10) is

$$\beta_i(t) = \beta_i - t\alpha_{iq}.$$

Let λ_i and φ_i denote the lower and upper bounds of the i th basic variable, respectively. The feasibility of the i th basic variable is maintained as long as the displacement t of the incoming variable is such that

$$\lambda_i \leq \beta_i - t\alpha_{iq} \leq \varphi_i. \quad (11)$$

It is straightforward to see that Equation (11) is satisfied, if t is the minimum of θ^+ and θ^- where

$$\theta^+ = \min_{\alpha_{iq} > 0} \{t_i\} = \min_{\alpha_{iq} > 0} \left\{ \frac{\beta_i - \lambda_i}{\alpha_{iq}} \right\} \quad (\text{type-A ratio}) \quad (12)$$

and

$$\theta^- = \min_{\alpha_{iq} < 0} \{t_i\} = \min_{\alpha_{iq} < 0} \left\{ \frac{\beta_i - \varphi_i}{\alpha_{iq}} \right\} \quad (\text{type-B ratio}). \quad (13)$$

However, to determine the final length of displacement (steplength) the individual bound of the selected incoming variable must also be taken into account. It results in the actual steplength of

$$\theta = \min\{\theta^+, \theta^-, u_q\}. \quad (14)$$

If the minimum is attained by a type-A ratio the outgoing variable becomes nonbasic at its lower bound, if the minimum is defined by a type-B ratio the outgoing variable exits at its upper bound. If $\theta = u_q$ there is no basis

change, x_q is moved to its opposite bound (bound flip). This is the *generalized ratio test*.

The development is similar if $t < 0$ is the improving displacement. In either case, the value of the objective function changes as

$$\hat{z} = z + \theta d_q, \quad (15)$$

where d_q is the reduced cost of the incoming variable (on the basis of which it was selected as an improving candidate).

If the basis is degenerate, a basic variable is at its lower or upper bound. In this case the numerator of the ratio test in Equation (12) or (13) can be zero if α_{iq} is of the “wrong” sign making the overall steplength $\theta = 0$. It also means that the incoming variable will remain at its bound maintaining the degeneracy of the corresponding basic position, unless a free variable enters at zero level. Thus, according to Equation (15), the value of the objective function remains unchanged. (Note, if the iteration is a bound flip the objective always improves.) Then it can happen that the ratio test of the new iteration also gives $\theta = 0$. It means, while the basis keeps changing the objective does not improve. After a number of such iterations the algorithm may return to an already visited basis. If the selection rule for the *entering variable* remains unchanged the algorithm will go through the same sequence of nonimproving steps indefinitely. This phenomenon is called *cycling*. There is also a possibility that a long sequence of zero steplength iterations may end in an improving one. This is called *stalling*.

Cycling prevents the simplex method from termination, while stalling “just” slows down the progress. From theoretical point of view, it is the possibility of cycling that has to be eliminated by the introduction of proper entering/exiting rules for a basis change. This will ensure the theoretical finiteness of the algorithm.

A basic solution can become degenerate in two ways. The trivial case is when the ever present unit matrix of logical variables is chosen as the starting basis and the $\mathbf{b}$ vector has some values (usually zeros) that are equal to one of the bounds of the corresponding logical variables. In this case the basis

will be degenerate. The other possibility is that a basis becomes degenerate as a result of an iteration. Namely, if the minimum in Equation (14) is not unique then we choose one of the positions in the tie and the corresponding basic variable leaves the basis. However, all other basic variables that are in the tie go to their bounds making the new basis degenerate.

There are two things to be noted about degeneracy.

1. Degeneracy does not always cause a nonimproving iteration. If the degenerate positions do not take part in the ratio test (if $\alpha_{iq} = 0$ or of the “wrong” sign) the steplength can be different from zero.
2. Degeneracy can disappear. During improving iterations (as above) basic values of the degenerate positions also get transformed. If the corresponding $\alpha_{iq} \neq 0$ the basic variable moves away from its boundary and can take a nondegenerate value.

ANTIDEGENERACY VERSIONS OF THE SIMPLEX METHOD

The possibility of cycling in both the primal and the dual simplex algorithm was early recognized and small examples were created [4,5] where cycling did occur. Even in 2004 a new example of cycling was published [6].

Cycling in the simplex method is possible only if degeneracy is present. At a degenerate basic solution (vertex) the number of active constraints is greater than the minimum necessary. It is illustrated in Fig. 1, where constraints a, c , and d are active in vertex D . Thus, D can be represented as the intersection of any two of these constraints. Therefore, the representation is not unique. Typically, a degenerate iteration just moves from one representation to another without improving the objective function. It has been shown [7,8] that the problem of exiting a degenerate vertex is as hard as the general linear programming problem.

Figure 1. A two dimensional convex polyhedron with degeneracy at vertex D .

Perturbation and Lexicographic Methods

Cycling cannot occur if the objective is improved in every iteration. It can “artificially” be guaranteed if, for instance, a controlled perturbation is applied to a degenerate basis. Dantzig [3] used this idea and developed the *perturbation method* for the simplex method which theoretically ensures that no basis is repeated. The proposed algorithm turned out to be fully equivalent to the *lexicographic simplex method* of Dantzig *et al.* [1]. Both algorithms require considerable amount of extra computations. Here, we just present the outline of the methods. For a complete discussion the reader is referred to the indicated sources.

The key feature of the methods is the rule how to choose the exiting variable in case the minimum in the ratio test is not unique. To break the tie rows of the inverse of the basis need to be used in the following way. For simplicity of the presentation (but without loss of generality), we assume all variables in the problem are nonnegative, $x_j \geq 0, \forall j$. Now the ratio test reduces to the evaluation of “ $\beta_i/\alpha_{iq}, \alpha_{iq} > 0$ ” type quantities. Let the inverse of the basis be denoted by $\mathbf{V} = [v_{ij}]$.

θ of the ratio test is defined by

$$\theta = \frac{\beta_p}{\alpha_{pq}} = \min_{\alpha_{iq} > 0} \left\{ \frac{\beta_i}{\alpha_{iq}} \right\}. \quad (16)$$

If the minimum ratio is attained for more than one i , index p (the basic position of the outgoing variable) is not uniquely defined.

Assume there are more $i = p_1, p_2, \dots$ indices that satisfy Equation (16). Choose from these i -s one to be the position of the exiting variable p such that

$$\frac{v_{p1}}{\alpha_{pq}} = \min_{i=p_1, p_2, \dots} \left\{ \frac{v_{iq}}{\alpha_{iq}} \right\}. \quad (17)$$

If p is still not unique a further ratio test is performed involving those positions that were tied in Equation (17). This recursive procedure is repeated until the actual ratio is uniquely defined. It will determine the exiting variables. The depth of recursion is no more than m as shown in Dantzig *et al.* [1] and Dantzig [3].

The heavy computational price that must be paid for both methods is the use of rows $p_1, p_2, \dots$ of the inverse of the basis. In the revised simplex method (which is the basis of all simplex implementations) is used the inverse is not explicitly available. As such, the required rows have to be determined by $\mathbf{e}_i^T \mathbf{B}^{-1}$ (often called *BTRAN*) type operations for the $i = p_1, p_2, \dots$ indices.

Bland's Rule

Bland has proposed and proved [9] an interesting finite version of the simplex method. The beauty of his method is its simplicity. It is commonly referred to as *Bland's rule*.

For the standard LP (minimization) the rule says the following. If a basis is not optimal then choose the variable x_q having the lowest index among improving candidates, that is,

$$q = \min\{j : d_j < 0\}.$$

In column q choose the outgoing basic variable on the basis of the ratio test. If there is a tie at the minimum select the one with the lowest index. In other words, the basic position of the outgoing variable is determined by

$$\begin{aligned} p &= \min \left\{ k : \alpha_{kq} > 0, \text{ and } \frac{\beta_k}{\alpha_{kq}} \right. \\ &= \left. \min \left\{ \frac{\beta_i}{\alpha_{iq}} : \alpha_{iq} > 0 \right\} \right\}. \end{aligned}$$

The selection of both the entering and leaving variables is the simplest possible.

As a result, the computational work per iteration is the smallest among all strategies. Unfortunately, Bland's rule does not perform well in practice. It usually requires many (often three to five times) more iterations than any other selection method. Therefore, it is not practical to use it. However, its theoretical importance remains undisputed.

Wolfe's "ad hoc" Method

There is a method that is theoretically sound (guarantees finite termination) and computationally attractive. It is Wolfe's *ad hoc method* [10]. In the following description it is assumed, again, that all variables of the problem are nonnegative and $\mathbf{B}$ is a feasible basis with $\boldsymbol{\beta} = \mathbf{B}^{-1}\mathbf{b} \geq \mathbf{0}$. The degeneracy set of basic variables is defined as

$$\mathcal{D} = \{i : \beta_i = 0\}.$$

If the basis is not optimal and the improving variable is x_q the solution is unbounded if x_q is not blocked by any of the basic variables, that is, $\alpha_{iq} \leq 0, \forall i$. This direction is called a *direction of recession*. If such a direction, restricted to the degenerate positions, can be found a nondegenerate iteration can be made. This observation is the key motivation of the *ad hoc* method. In other words, a direction of recession is sought for $\mathcal{D}$.

The algorithm uses the notion of *depth of degeneracy*. At the outset every position in $\mathcal{D}$ has a depth of zero. Every time a position with the largest depth undergoes a "virtual perturbation" the degeneracy deepens. On the other hand, when a direction of recession is found for the subproblem consisting of the deepest positions, degeneracy shallows. The only thing that needs to be noted of a position in $\mathcal{D}$ is its depth which will be denoted by $g_i, i \in \mathcal{D}$.

Initialization: Set $g_i = 0, i \in \mathcal{D}$. Assuming that an improving candidate x_q has been selected and α_q is available, one iteration of the algorithm can be described by the following steps.

- Step 1. For each i with $\beta_i = 0$, replace β_i by a small positive random number δ_i . Note, after random choice of δ_i the perturbed values remain feasible.

Replace g_i by $g_i + 1$ to signify that degeneracy has deepened.

- Step 2. Let $G = \max_i \{g_i\}$. Perform a ratio test with positions for which $g_i = G$. If a pivot row p is found with $\theta = \beta_p / \alpha_{pq}$ go to Step 3, otherwise, as all $\alpha_{iq} \leq 0, i \in \mathcal{D}$, go to Step 4.
- Step 3. Apply a special update. The outgoing variable leaves the basis at its exact bound. The basic variables in $\mathcal{D}$ are updated such that for any position with $g_i < G$ everything remains unchanged. For positions with $g_i = G$ replace β_i by $\beta_i - \theta \alpha_{iq}$ for $i \neq p$ and β_p by θ . Keep $g_p = G$. Basic variables outside $\mathcal{D}$ remain unchanged as the current pivot step corresponds to a degenerate iteration for the original problem. Choose a new incoming column and return to Step 1. If none can be chosen the current basis is optimal. Solution needs to be recomputed with restored bounds for variables in $\mathcal{D}$.
- Step 4. As a pivot row was not found, we have a direction of recession for the subproblem consisting of rows with $g_i = G$, consequently, the degeneracy has shallowed. If $G > 0$, for each i with $g_i = G$ replace β_i by zero and g_i by $g_i - 1$. Return to Step 2. Otherwise, if $G = 0$ the problem is unbounded.

From the above description it can be seen that degeneracy can deepen if the minimum ratio is not unique in the ratio test. However, as the iterations are always nondegenerate, the number of elements in the deeper level of degeneracy will be at least one less. It can go down no deeper than m where just one element can be present. The purpose of the random choice of the perturbation is to reduce the chance of deepening.

An important advantage of the method is that it does not introduce infeasibilities. Therefore, when a real nondegenerate step is made the solution remains feasible. Further advantages are the moderate increase in the

computational effort and the simplicity of implementation.

The *ad hoc* method performs very well in practice. The depth of degeneracy hardly ever goes beyond 2 if the perturbations are properly selected. Therefore, the amount of extra computations remains very moderate.

Heuristics

Interestingly, cycling hardly ever occurs in practice. At the same time, stalling is a relatively frequent phenomenon unless some strategy is used to shorten it. Ideas that help prevent cycling are usually beneficial also in case of stalling.

Examples of cycling use a predefined column selection rule. As there are many column selection (pricing) strategies [2, pp. 184–203] one can try to use different pricing in subsequent iterations. Depending on what combination of strategies is used it can work quite efficiently. However, there are more elaborate techniques that directly target degeneracy. Some of them suggest how to select incoming variables so that the chance of finding nondegenerate pivots increases [2, pp. 232–234], others deal with row selection [11]–[13] and use some form of numerical perturbation of degenerate positions. Most recently, “bound shifting” [2, pp. 243–244] has emerged as a simple but effective method to get through degenerate bases.

There are also techniques that aim at improving the efficiency of the simplex method while, as a side effect, they are quite powerful in making improving iterations even in the presence of degeneracy. Just to mention a few, the “steepest edge” type column selection strategies [11,14] try to select columns that promise the largest improvement of the objective function. Advanced pivot row selection methods in phase 1 of the primal simplex [15], [2, pp. 203–227], and in both phases of the dual [2, pp. 270–291; 16] have the capability to bypass degenerate pivots during row selection.

FURTHER READINGS

The literature has actively discussed various issues of degeneracy since 1952. Interested readers may find in Charnes [17], Greenberg

[18], Greenberg [19], Gal and Geue [20], and Gass and Vinjamuri [21] further details of degeneracy in the simplex method.

Experience has shown that LP relaxations of network and combinatorial optimization problems can be quite degenerate. In this category some excellent readings are Cunningham [22], Ryan and Osborne [23], and Goldfarb *et al.* [24].

DELAYED RENEWAL PROCESSES

NILAY TANIK ARGON
Department of Statistics and
Operations Research,
University of North Carolina,
Chapel Hill, North Carolina

Let $\{X_n, n \geq 1\}$ be a sequence of independent nonnegative random variables such that $F(x) = \Pr\{X_1 \leq x\}$, for $x \geq 0$, and $G(x) = \Pr\{X_n \leq x\}$, for $x \geq 0$ and $n \geq 2$. Let also $S_0 = 0$ and $S_n = \sum_{i=1}^n X_i$, for $n \geq 1$, and define

$$N_D(t) = \sup\{n \geq 0 : S_n \leq t\}.$$

The stochastic process $\{N_D(t), t \geq 0\}$ is called a *delayed renewal process*. Hence, a delayed renewal process is essentially a renewal process except that the first interrenewal time has a distribution different from the others.

Example 1. Let $\{Z(t), t \geq 0\}$ be a continuous-time Markov chain with state space $S = \{0, 1, 2, \dots\}$. Let $N_D(t)$ be the number of visits to state $i \in S$ during $(0, t]$ starting from state $j \in S$ at time zero. If $i = j$, then $\{N_D(t), t \geq 0\}$ is a standard renewal process; otherwise, it is a delayed renewal process.

We will see in the following that delayed renewal processes possess almost all the properties of standard renewal processes.

TRANSIENT BEHAVIOR

To avoid trivialities, assume that $G(0) < 1$. We can then obtain the following result, which shows that $N_D(t)$ is a nondefective (or proper) random variable for any given $t \geq 0$.

Theorem 1. $N_D(t) < \infty$ with probability one for all $t \geq 0$.

We next study the distribution of $N_D(t)$ for some given $t \geq 0$. First let G_k be the k -fold convolution of G with itself, where

$$G_0(t) = 1$$

$$G_k(t) = \int_0^t G(t-u) dG_{k-1}(u), \text{ for } k \geq 1.$$

Theorem 2. Let $F * G_k(t)$ be the convolution of F and G_k , that is,

$$F * G_k(t) = \int_0^t F(t-u) dG_k(u), \text{ for } k \geq 0.$$

Then, for any given $t \geq 0$, we have

$$\Pr\{N_D(t) = 0\} = \Pr\{S_1 > t\} = 1 - F(t)$$

$$\Pr\{N_D(t) = k\} = \Pr\{S_k \leq t\} - \Pr\{S_{k+1} \leq t\}$$

$$= F * G_{k-1}(t) - F * G_k(t),$$

$$\text{for } k \geq 1.$$

It is also of interest to obtain an expression for the expected value of $N_D(t)$ for a given $t \geq 0$. Let $M_D(t) = \mathbb{E}[N_D(t)]$ be the renewal function of the delayed renewal process. Let also $M(t) = \mathbb{E}[N(t)]$ be the renewal function of a standard renewal process $\{N(t), t \geq 0\}$ with interrenewal distribution G . Conditioning on X_1 , we get

$$\mathbb{E}[N_D(t)|X_1 = x] = \begin{cases} 0 & \text{if } x > t \\ 1 + M(t-x) & \text{if } x \leq t. \end{cases}$$

Then, unconditioning, we get

$$M_D(t) = \int_0^\infty \mathbb{E}[N_D(t)|X_1 = x] dF(x)$$

$$= \int_0^t (1 + M(t-x)) dF(x)$$

$$= F(t) + \int_0^t M(t-x) dF(x). \quad (1)$$

Taking Laplace–Stieltjes transform (LST) of both sides of this equation yields

$$\tilde{M}_D(s) = \tilde{F}(s) + \tilde{M}(s)\tilde{F}(s),$$

where $\tilde{M}_D$, $\tilde{F}$, and $\tilde{M}$ denote the LST of M_D , F , and M , respectively. Now, using the fact that $\tilde{M}(s) = \tilde{G}(s)/(1 - \tilde{G}(s))$ (e.g., Section 8.3 in Kulkarni [1]), we get

$$\tilde{M}_D(s) = \frac{\tilde{F}(s)}{1 - \tilde{G}(s)}, \quad (2)$$

where $\tilde{G}$ denotes the LST of G . This expression can be useful in computing the renewal function of a delayed renewal process. However, unlike its counterpart for a standard renewal process, it does not uniquely characterize the underlying delayed renewal process.

LIMITING BEHAVIOR

Assume that $F(\infty) = 1$ and $G(\infty) = 1$. This assumption ensures that $\lim_{t \rightarrow \infty} N_D(t) = \infty$ with probability one. The following theorem provides the rate at which $N_D(t)$ goes to infinity as t becomes large. Let τ be the mean of X_n for all $n \geq 2$.

Theorem 3. *With probability one,*

$$\frac{N_D(t)}{t} \rightarrow \frac{1}{\tau} \text{ as } t \rightarrow \infty \text{ for } \tau < \infty.$$

The next theorem shows that the renewal function $M_D(t)$ goes to infinity (as $t \rightarrow \infty$) at the same rate as $N_D(t)$ does.

Theorem 4.

$$\frac{M_D(t)}{t} \rightarrow \frac{1}{\tau} \text{ as } t \rightarrow \infty \text{ for } \tau < \infty.$$

When the renewal argument is applied to a delayed renewal process, the outcome is generally an integral equation that takes the following form:

$$H_D(t) = C(t) + \int_0^t H(t-u) dF(u), \quad (3)$$

where $C(t)$ is a known function, $H(t)$ is a function associated with the standard renewal process with interrenewal distribution G , and $H_D(t)$ is the function to be determined. In the previous section, we have already seen one use of such an equation. In particular, Equation (1), which is an integral equation that satisfies the form given by Equation (3), yielded an expression for the LST of the renewal function (Eq. 2). The following theorem provides a result on the limiting behavior of $H_D(t)$.

Theorem 5. *Suppose that $H_D(t)$ is a function that satisfies Equation (3). If $C(t)$ and $H(t)$ are bounded functions with finite limits for large t , then $\lim_{t \rightarrow \infty} H_D(t) = \lim_{t \rightarrow \infty} C(t) + \lim_{t \rightarrow \infty} H(t)$.*

Theorem 5 can be useful for the asymptotic analysis of a delayed renewal process because $C(t)$ is generally a function with a known finite limit. Furthermore, in most cases, $H(t)$ is a function associated with a standard renewal process, and hence one could apply the key renewal theorem for standard renewal processes to obtain its limit. The following example demonstrates the use of Theorem 5.

Example 2. Let $B_D(t) = S_{N_D(t)+1} - t$ be the *remaining life* for the delayed renewal process at time $t \geq 0$. We will use Theorem 5 to show that the limiting distribution for $B_D(t)$ is the same as the limiting distribution for $B(t)$, which is the remaining life for a standard renewal process $\{N(t), t \geq 0\}$ with interrenewal time distribution G . First, let $H_D(t) = \Pr\{B_D(t) > x\}$ and $H(t) = \Pr\{B(t) > x\}$ for some $x > 0$ and $t \geq 0$. Conditioning on X_1 , we get

$$\Pr\{B_D(t) > x \mid X_1 = u\} = \begin{cases} H(t-u) & \text{if } 0 \leq u \leq t \\ 0 & \text{if } t < u \leq x+t \\ 1 & \text{if } u > x+t. \end{cases}$$

Unconditioning, we get

$$H_D(t) = \int_0^\infty \Pr\{B_D(t) > x \mid X_1 = u\} dF(u)$$

$$\begin{aligned}
 &= \int_0^t H(t-u) dF(u) + \int_{x+t}^{\infty} dF(u) \\
 &= 1 - F(x+t) + \int_0^t H(t-u) dF(u). \quad (4)
 \end{aligned}$$

Note that Equation (4) is of the form given in Equation (3) with $C(t) = 1 - F(x+t)$. Hence, using the fact that $\lim_{t \rightarrow \infty} C(t) = 0$ together with Theorem 5 yields

$$\begin{aligned}
 \lim_{t \rightarrow \infty} H_D(t) &= \lim_{t \rightarrow \infty} H(t) \\
 &= \frac{1}{\tau} \int_x^{\infty} (1 - G(u)) du. \quad (5)
 \end{aligned}$$

See for example, Section 8.6 of Kulkarni [1] for a proof of Equation (5).

Remark 1. As expected, the asymptotic results above do not contain the first interrenewal time distribution F .

EQUILIBRIUM RENEWAL PROCESSES

In this section, we consider a delayed renewal process for which F is the limiting distribution of excess life (Eq. 5) for a standard renewal process with interrenewal distribution G . To be more specific, suppose that

$$F(x) = \frac{1}{\tau} \int_0^x (1 - G(u)) du, \text{ for } x > 0. \quad (6)$$

We call this special delayed renewal process an *equilibrium renewal process* and denote it by $\{N_e(t), t \geq 0\}$. We first study the renewal function $M_e(t) = \mathbb{E}[N_e(t)]$. Using Equation (6), we find the LST of F as

$$\tilde{F}(s) = \frac{1 - \tilde{G}(s)}{\tau s}.$$

Now plugging this into Equation (2) gives $\tilde{M}_e(s) = 1/(\tau s)$, where $\tilde{M}_e$ is the LST of M_e . Inverting $\tilde{M}_e(s)$, we obtain the result given below.

Theorem 6. $M_e(t) = t/\tau$ for all $t \geq 0$.

Theorem 6 implies that $M_e(t)/t = 1/\tau$ for all $t \geq 0$, which is only asymptotically true for

other delayed and standard renewal processes, as in Theorem 4. The next theorem provides the distribution of the excess life $B_e(t)$ at time $t \geq 0$ for the equilibrium renewal process $\{N_e(t), t \geq 0\}$.

Theorem 7. For all $t \geq 0$ and $x > 0$,

$$\Pr\{B_e(t) \leq x\} = F(x) = \frac{1}{\tau} \int_x^{\infty} (1 - G(u)) du.$$

Thus, the excess life distribution at any given time $t \geq 0$ for an equilibrium renewal process is the same as the limiting distribution of excess life in a delayed or standard renewal process with the same interrenewal time distribution G . This leads to the following result, which explains why we call $\{N_e(t), t \geq 0\}$ an equilibrium renewal process.

Theorem 8. $\{N_e(t), t \geq 0\}$ has stationary increments.

Example 3. Suppose that $G(x) = 1 - e^{-\lambda x}$, for $x \geq 0$, that is the interrenewal times after the first renewal are exponentially distributed with rate λ . Suppose also that F satisfies Equation (6) and hence the resulting delayed renewal process is an equilibrium renewal process. In this case, it is easy to see that F and G are the same, and hence the equilibrium renewal process is indeed a stationary Poisson process.

FURTHER READING

The treatment of delayed renewal processes in this article follows Kulkarni [1] fairly closely. For omitted proofs and further examples, the interested reader is referred to Çinlar [2], Kulkarni [1], Ross [3], and references therein.

DEMAND RESPONSIVE TRANSPORTATION

SOPHIE N. PARRAGH
KARL F. DOERNER
RICHARD F. HARTL
Department of Business
Administration, University
of Vienna, Vienna, Austria

Demand responsive transportation systems are flexible (public) transportation services in which vehicle routes and schedules are generated on the basis of user requests. Demand responsive transportation also arises in private systems such as in on-demand aircraft services [1,2]. Existing public demand responsive systems are mostly dedicated to the transportation of the disabled, elderly, or ill [3]. In order to increase the efficiency of these systems, OR models and optimization techniques have been developed. In this article we focus on those passenger transportation problems where user requests consist of paired pickup and delivery locations, also known as *dial-a-ride problems* (DARPs). They fall under the broad umbrella of vehicle routing problems with pickup and delivery [4]. Classical pickup and delivery problems (PDPs) deal with the transportation of goods while DARPs deal with passenger transportation. Hence, DARPs focus on quality of service related issues. Following another classification scheme [5], DARPs belong to the one-to-one problem class. DARPs have received considerable attention in the literature. The first publications in the field of passenger transportation date back to the late 1960s and early 1970s [6–9]. A rather recent survey on DARPs was written by Cordeau and Laporte [10].

Following Cordeau [11], the basic DARP is modeled on a complete directed graph $G = (V, A)$, where V is the set of all vertices and A the set of all arcs. For each arc (i, j) a nonnegative travel cost c_{ij} and a

nonnegative travel time t_{ij} are considered. A total of n customer requests, each consisting of a pickup and delivery vertex pair $(i, n+i)$, are to be served by a set K of m identical vehicles with a capacity of C ; P denotes the set of pickup vertices and D the set of delivery vertices. All vehicles are stationed at a central depot denoted by 0 (origin depot) and $2n+1$ (end depot). Furthermore, every route has to be completed within a maximum route duration limit T . At every pickup vertex a certain number of passengers ($q_i > 0$) waits to be transported. The demand at every delivery vertex is equal to $q_{n+i} = -q_i$. The pickup vertex (origin) and/or the delivery vertex (destination) are associated with time windows $[e_i, l_i]$. In the case where different types of requests are considered, outbound requests, that is, from home to an appointment, have a tight time window only at the destination; and inbound requests, that is, from an appointment back home, have a tight time window only at the origin. The service time for loading or unloading operations at each vertex is denoted by d_i . Beginning of service at each vertex i by vehicle k , denoted as B_i^k , and the load when leaving vertex i with vehicle k , denoted as Q_i^k , are to be determined. The ride time of a client is calculated by $L_i^k = B_{n+i}^k - (B_i^k + d_i)$. In order to limit user inconvenience caused by long detours, a maximum user ride time $\bar{L}$ has to be respected. Finally, the binary variable x_{ij}^k is used to indicate whether arc (i, j) is traversed by vehicle k . The basic DARP can thus be formulated as the following 3-index program (based on Cordeau [11]):

$$\sum_{i \in V} \sum_{j \in V} \sum_{k \in K} c_{ij} x_{ij}^k, \quad (1)$$

subject to,

$$\sum_{i \in V} \sum_{k \in K} x_{ij}^k = 1 \quad \forall j \in P, \quad (2)$$

$$\sum_{j \in V} x_{ij}^k - \sum_{j \in V} x_{n+i,j}^k = 0 \quad \forall i \in P, k \in K, \quad (3)$$

$$\sum_{j \in V} x_{0j}^k = 1 \quad \forall k \in K, \quad (4)$$

$$\sum_{j \in V} x_{ji}^k - \sum_{j \in V} x_{ij}^k = 0 \quad \forall i \in P \cup D, k \in K, \quad (5)$$

$$\sum_{i \in V} x_{i,2n+1}^k = 1 \quad \forall k \in K, \quad (6)$$

$$x_{ij}^k = 1 \Rightarrow B_j^k \geq B_i^k + d_i + t_{ij} \quad \forall i \in V, j \in V, k \in K, \quad (7)$$

$$x_{ij}^k = 1 \Rightarrow Q_j^k \geq Q_i^k + q_j \quad \forall i \in V, j \in V, k \in K, \quad (8)$$

$$L_i^k = B_{n+i}^k - (B_i^k + d_i) \quad \forall i \in P, k \in K, \quad (9)$$

$$B_{2n+1}^k - B_0^k \leq T \quad \forall k \in K, \quad (10)$$

$$e_i \leq B_i^k \leq l_i \quad \forall i \in V, k \in K, \quad (11)$$

$$t_{i,n+i} \leq L_i^k \leq \bar{L} \quad \forall i \in P, k \in K, \quad (12)$$

$$\max\{0, q_i\} \leq Q_i^k \leq \min\{C, C + q_i\} \quad \forall i \in V, k \in K, \quad (13)$$

$$x_{ij}^k \in \{0, 1\} \quad \forall i \in V, j \in V, k \in K. \quad (14)$$

The objective function (1) minimizes total routing costs. Constraints (2–6) ensure that each request is served exactly once; each origin is visited by the same vehicle as its destination; and each vehicle's route starts at the origin depot and ends at the destination depot. Load propagation and consistency with respect to time variables is guaranteed by inequalities (7) and (8). User ride times are set by equalities (9). Maximum route duration restrictions, time window compliance, and maximum ride time limits are enforced by constraints (10–12); constraints (12) (together with (9)) also ensure that each request's pickup location is visited before its delivery location. Capacity limits are imposed by Equation (13).

A number of different versions of this standard DARP have been considered in the literature. Owing to strict space limitations we do not claim that the following overview of real-world aspects and solution methods in the field of DARPs is exhaustive. We, however, hope to provide a useful selection of articles, covering all important aspects.

REAL-WORLD ASPECTS

Most publications consider a static variant of the DARP (all transportation requests are known in advance). Taking the above stated 3-index formulation as a starting point, a number of variations exist. Many authors do not consider a maximum user ride time limit; instead time windows are placed on both the pickup and the delivery point, which yields an implicit (and, in most cases, more restrictive) ride time limit [12–14]. The according problem can be defined by removing all ride time related constraints given by Equations (9) and (12), and by introducing the following additional set of constraints on the beginning of service variables:

$$B_i^k \leq B_{n+i}^k \quad \forall i \in P, k \in K. \quad (15)$$

It ensures that user i 's pickup location is visited before his/her delivery location [previously enforced by Equations (9) and (12)].

In addition, different vehicles may travel at different speeds and travel costs may vary according to weight, size, and equipment. These two aspects are easily accommodated in the 3-index model. Homogeneous travel times and costs are simply replaced by vehicle dependent ones (c_{ij}^k, t_{ij}^k). However, vehicles may also differ with respect to the number of persons that can be transported. This aspect can be handled by adding a superscript k to the capacity limit C^k to distinguish the different vehicles. Finally, in many real-life applications, especially in the transportation of the handicapped or the ill, different transportation modes have to be considered. At least three such modes can be distinguished: seated, on a bed, or in a wheelchair. It leads to the introduction of a set of transportation modes R and the distinction of different capacities for each mode: C^r . Then, each user demands a place in the according mode q_i^r . In combination with several vehicle types, each vehicle k disposes of $C^{r,k}$ space for transportation mode r . Toth and Vigo [15] distinguished between seated passengers and passengers in wheelchairs; Beaudry *et al.* [16] provided for three types of passengers (seated, on a bed, and in a wheelchair); Parragh *et al.* [17] considered four modes of transportation

($R = \{0, 1, 2, 3\}$; 0 = staff seat, 1 = patient seat, 2 = bed, 3 = wheelchair). An accompanying person may also be present. They should use staff seats, may, however, also sit on patient seats or the bed; a seated patient should use the patient seat, may, however, also sit on the bed. Introducing variables $Q_i^{r,k}$, giving the load of resource r on vehicle k when leaving vertex i , these so-called upgrading options are modeled by the following inequalities (replacing Equations (8) and (13) in the above formulation):

$$x_{ij}^k = 1 \Rightarrow Q_j^{r,k} \geq Q_i^{r,k} + q_j^r \quad \forall i, j \in V, k \in K, r \in R, \quad (16)$$

$$\sum_{r'=r}^2 Q_i^{r',k} \leq \sum_{r'=r}^2 C^{r',k} \quad \forall i \in V, k \in K, r \in R \setminus \{3\}, \quad (17)$$

$$Q_i^{3,k} \leq C^{3,k} \quad \forall i \in V, k \in K. \quad (18)$$

Finally, different real-world situations also call for different objective functions. Many authors only consider user inconvenience in terms of constraints, that is, time windows, maximum (excess) user ride times, or maximum waiting times, while minimizing a cost related objective. Others incorporate the user inconvenience aspect into the objective function, either instead of or besides a cost related term. An objective function incorporating the difference between the actual and the shortest possible or direct ride times is considered by Bodin and Sexton [18] (in addition to the difference between actual and desired drop-off times), by Diana and Dessouky [19] (in addition to the total distance traveled and vehicle idle times), and by Jørgensen *et al.* [20] (in addition to route duration, total ride time, waiting time, time window, and other time related violations).

EXACT SOLUTION APPROACHES

Models (1–14), leaving aside route duration constraint (10), can be reformulated in more efficient ways. Ropke *et al.* [21] proposed two 2-index formulations for the PDP and the

DARP. Both exploit the fact that a homogeneous set of vehicles is considered, that is, time and load related conditions do not depend on which vehicle travels along which arc. All vehicle routes are thus defined on a single set of arc variables x_{ij} . The first formulation explicitly formulates all time- and load related constraints using time B_i and load Q_i variables (beginning of service constraints (7) also take care of subtour elimination; ride time constraints (9) and (12) take care of precedence). In the second formulation, these constraints are reformulated in the form of precedence constraints [22],

$$\sum_{i,j \in S} x_{ij} \leq |S| - 2 \quad S \in \mathcal{S}, \quad (19)$$

capacity constraints,

$$\sum_{i,j \in S} x_{ij} \leq |S| - \max\{1, \lceil |q(S)|/C \rceil\} \quad S \subseteq P \cup D, |S| \geq 2, \quad (20)$$

and infeasible path constraints,

$$\sum_{(i,j) \in A(F)} x_{ij} \leq |A(F)| - 1 \quad F \in \mathcal{F}, \quad (21)$$

where S denotes a vertex set; $\mathcal{S}$ denotes the set of all vertex subsets $S \subseteq V$ such that $0 \in S$, $2n+1 \notin S$, and $i \notin S$, $n+i \in S$ for at least one request i ; $q(S) = \sum_{i \in S} q_i$, $\mathcal{F}$ denotes the set of all time-infeasible paths, and $A(F)$ all arcs that are part of the infeasible path F . The advantage of the second reformulation is the reduced number of variables. Its major drawback consists in a loss of flexibility: time or capacity related issues can no longer be easily integrated into the objective function. Ropke *et al.* [21] used each 2-index formulation as the basis for a branch-and-cut algorithm, separating several additional families of valid inequalities. The latter proves to work better. Both outperform the branch-and-cut algorithm based on the 3-index formulation [11]. The largest instance solved to optimality in Cordeau [11] comprises 36 requests; Ropke *et al.* [21] solved instances with up to 96 requests. On the basis of these findings, Parragh [23] developed a 3-index and a 2-index formulation for the DARP with

heterogeneous users and vehicles, including upgrading (see above). The introduction of artificial start and end depots (one per vehicle) makes a 2-index formulation possible. Let $D_o = \{2n + 1, \dots, 2n + m\}$ denote the set of vehicle start depots and $D_d = \{2n + m + 1, \dots, 2n + 2m\}$ the set of vehicle end depots. The correct pairing of two depots $\{2n + k, 2n + m + k\}$ is ensured by

$$\sum_{i \in U} \sum_{j \notin U} x_{ij} \geq 1 \quad \forall U \in \mathcal{U}. \quad (22)$$

Here $\mathcal{U}$ is defined as the set of all vertex subsets $U \subseteq V$, such that for exactly one $k \in K$ the origin depot $2n + k \in U$ and the destination depot $2n + m + k \notin U$, while for all other $l \in K \setminus \{k\}$ origin depots $2n + l \notin U$ and destination depots $2n + m + l \in U$. To handle the heterogeneous capacity constraints, let $\mathcal{H}$ denote the set of infeasible paths $H = \{j_1, \dots, j_h\}$ with respect to load violations, such that $j_1 \in D_o$. A constraint similar to Equation (21) is used. Also in this case, the reformulation as a 2-index model leads to a more efficient branch-and-cut algorithm. The largest instance solved to optimality comprises 40 requests.

Other research in the field of exact methods for the DARP predominantly belongs to the dynamic programming domain and deals with single-vehicle versions of the DARP. The dynamic programming algorithm of Psaraftis [24] takes care of service quality by means of maximal position shift constraints compared to a first-come first-serve visiting policy; it is also applied to the dynamic case. A modified version of this algorithm, considering time windows, applies forward instead of backward recursion [25]. In a further forward dynamic programming algorithm [26], possible states are reduced by eliminating those that are incompatible with respect to vehicle capacity, precedence, and time window restrictions.

HEURISTIC SOLUTION APPROACHES

In a heuristic context, once the visiting order of pickup and delivery locations has been decided upon, the scheduling subproblem,

setting the beginning of service at each node, has to be solved. Especially in the context of maximum route duration and maximum user ride time constraints, its solution is not as straightforward as one may assume. The route duration part has already been investigated in the context of the vehicle routing problem with time windows: Savelsbergh [27] introduced the notion of forward time slack. It gives the amount of time by which the beginning of service at the origin depot can be shifted forward, yielding a schedule of minimum duration. On the basis of the forward time slack, Cordeau and Laporte [28] developed an eight-step evaluation scheme. It calculates a forward time slack for each pickup location part of the route to be evaluated. It is thus able to check whether or not a given node sequence can be visited in a feasible way with respect to time window, route duration, and ride time constraints. However, it does not necessarily yield the minimum average ride time for a given route. This issue is addressed in Parragh *et al.* [29]; the scheme of Parragh *et al.* [29] yields shorter ride times, but, in some cases, a route is considered as infeasible although a feasible schedule would exist if ride time increases were allowed. Also other authors have addressed the scheduling issue. Hunsaker and Savelsbergh [30], for example, proposed a fast feasibility check for the DARP, dealing with time window, waiting time, as well as ride time restrictions; it is also more restrictive in terms of feasibility than the evaluation scheme of Cordeau and Laporte [28].

Over the past decades, a large number of heuristic algorithms have been proposed for DARPs. Heuristic methods in the field of vehicle routing classify into classical heuristics and metaheuristics [31]. Classical heuristic methods comprise two-phase heuristics, construction heuristics, and improvement methods. The following overview of heuristic solution methods follows this classification scheme. We distinguish between heuristics for static and heuristics for dynamic and/or stochastic variants.

Heuristics for Static Variants

The term *static* indicates that all requests are known in advance of the planning. This

assumption is made by all research works summarized in the following.

Two-Phase Heuristics. One of the first heuristic solution procedures for a static multivehicle DARP was proposed by Cullen *et al.* [32]. They developed an interactive algorithm that follows the cluster-first route-second approach. It is based on a set partitioning formulation solved by means of column generation. The location-allocation subproblem is only solved approximately. Other cluster-first route-second approaches for different versions of the DARP are due to authors [18,33–36]. A classical cluster-first route-second algorithm was proposed by Borndörfer *et al.* [13]. Here, the clustering as well as the routing problem are modeled as set partitioning problems. The clustering problem can be solved optimally while the routing subproblems are solved approximately by a branch-and-bound algorithm (only a subset of all possible tours is used). An optimization-based miniclustering algorithm is presented in Ioachim *et al.* [37]. It uses column generation to obtain miniclusters and an enhanced initialization procedure to decrease processing times. Also the case of multiple depots is considered. The idea of miniclusters has been employed by a number of authors [12,38–40].

Construction Heuristics. A heuristic routing and scheduling algorithm for the single-vehicle DARP using Benders decomposition is described in Sexton and Bodin [41,42]. The scheduling problem can be solved optimally; the routing problem is solved with a heuristic algorithm. A minimum spanning tree heuristic for the single-vehicle case is described in Psaraftis [43]. Jaw *et al.* [44] proposed a sequential insertion procedure for the multivehicle case: customers are ordered according to increasing earliest time for pickup and are inserted using the cheapest feasible insertion criterion. Other construction heuristics are described by authors [45–48]. A regret insertion algorithm is due to Diana and Dessouky [19]. Regret insertion is also subject to analysis in a study by Diana [49] in order to determine why the performance of this heuristic is superior to that of other insertion rules. In

addition, beam search was used to solve the multivehicle DARP [50].

Construction-Improvement Heuristics. For the single-vehicle DARP, adaptations of 2-opt and 3-opt heuristics [51] and a 2-opt improvement scheme switching between optimizing and sacrificing phases [52] were developed. The construction-improvement concept was also used to solve multivehicle DARPs [14,53,54]. In the improvement phase operators such as trip insertion, exchange, and move are employed.

Metaheuristics. Among the most popular metaheuristic concepts applied to the DARPs are simulated annealing [55,56], tabu search [28,57,58], and genetic algorithms [20,59,60]. Toth and Vigo [15] described a further local search-based metaheuristic, a tabu thresholding algorithm, employing the neighborhoods defined in Toth and Vigo [53]. In Parragh *et al.* [61] a variable neighborhood search algorithm is described and applied to different versions of the DARP. It is compared to the tabu search algorithm of Cordeau and Laporte [28] and the genetic algorithm of Jørgensen *et al.* [20]. Similar variable neighborhood search algorithms are employed in Parragh [23] and Parragh *et al.* [17] for heterogeneous variants of the DARP and in combination with path relinking to a biobjective version [29].

Heuristics for Dynamic and Stochastic Variants

The term *dynamic* indicates that routing is done in real time, that is, new requests come in during the day and have to be scheduled into existing routes; *stochastic* versions integrate knowledge about the future in terms of probability functions into the planning.

Two Phase-Heuristics. In a cluster-first route-second framework, considering only the most urgent requests in a dynamic context, Colorni and Righini [62] solved the routing subproblems to optimality with a branch-and-bound algorithm. Also Caramia *et al.* [63] iteratively solved the single-vehicle subproblems to optimality, using a dynamic programming algorithm. Another cluster-first route-second approach, applying

dynamic programming in the routing phase, assigns new transportation requests to clusters according to least cost insertion [64]. Teodorovic and Radivojevic [65] proposed a two-stage fuzzy logic-based heuristic algorithm also following the cluster-first route-second idea. The first approximate reasoning heuristic decides which vehicle a new request is assigned to. The second heuristic handles the adjustment of the vehicle's route.

Construction Heuristics. Daganzo [66] analyzed three different insertion strategies: visiting the closest stop next; visiting the closest origin or the closest destination in alternating order; and inserting delivery locations only after a fixed number of users have been picked up. A multiobjective approach is followed in Madsen *et al.* [67], discussing an insertion-based algorithm called REBUS. The objectives considered are the total driving time, the number of vehicles, the total waiting time, the deviation from promised service times as well as cost. Fu [68] developed a parallel insertion algorithm for a stochastic version of the DARP, considering time-dependent travel times. The same author proposed a simulation environment to test future solution methods [69].

Construction-Improvement Heuristics. Coslovich *et al.* [70] proposed a two-phase insertion heuristic. A simple insertion procedure allows for quick answers with respect to inclusion or rejection of a new customer. The initial solution is improved by means of local search using 2-opt arc swaps. A dynamic DARP in a stochastic environment is considered in Xiang *et al.* [71], taking into account travel time fluctuations, absent customers, vehicle breakdowns, cancellation of requests, traffic jams, and so on. To solve this complex problem situation the heuristic of Xiang *et al.* [14] is adapted to the dynamic case. Horn [72] provided a software environment for fleet scheduling and dispatching of demand responsive services. Incoming requests are inserted into existing routes according to least cost insertion. A steepest descent improvement phase is run periodically. The system was tested in the modeling framework LITRES-2 [73].

Metaheuristics. Attanasio *et al.* [74] adapted the tabu search of Cordeau and Laporte [28] to the dynamic DARP by means of parallelization; and in Beaudry *et al.* [16] it is used to solve a dynamic DARP with additional real-world constraints. In Hanne *et al.* [75] a dynamic in-hospital version is solved with an evolutionary algorithm. A tabu search for a probabilistic DARP is discussed and compared to a construction-improvement heuristic in Ho and Haugland [76]. Berbeglia *et al.* [77] introduced a hybrid algorithm for the dynamic DARP, combining tabu search with constraint programming. Finally, a scenario-based variable neighborhood search algorithm, a multiple plan approach and a multi-scenario approach, both integrating a variable neighborhood search algorithm, for the dynamic stochastic DARP are discussed in Schilde *et al.* [78].

SUMMARY

State-of-the-art exact algorithms developed for the static DARP solve some instances with up to 96 requests [21]. However, the size of a test instance is not a really meaningful measure as tightly constrained instances are easier to solve than those with less tight constraints. In case of heuristic and metaheuristic methods, large parts of the proposed solution procedures are motivated by real-world problem situations. They differ regarding problem type (single and multidepot, homogeneous and heterogeneous fleet), constraints, and objective(s). Most of the solution algorithms for the dynamic DARP are based on repeated calls to static solution routines. In both cases, almost all solution methodologies were either tested on different data sets or, in the case where the same data set was used, varying, problem-specific (real-world) assumptions were made. Therefore, in either case, it is not possible to specify the best method developed so far. An overview of available test data sets can be found in Parragh *et al.* [4] and Parragh [79].

DESCRIBING DECISION PROBLEMS BY DECISION TREES

OPERATIONAL AND STRATEGIC DECISIONS

For operational decisions, Deming's four-step process (plan/do/check/act) involves

1. checking where actual system behavior differs from desired behavior,
2. analyzing the causes of these discrepancies,
3. planning corrective actions, and
4. implementing corrective action.

This is commonly represented as the Deming cycle (Fig. 1).

The Deming cycle is a scientifically informed trial and error process focused on continuous improvement. But when there are large time lags (which creates uncertainty about which interventions are helpful), it is useful to think through alternatives, think about future uncertainties, and think carefully about long term values. These time lags and uncertainties are especially common in strategic contexts. In these contexts, decision analysis (with decision trees) can be superior to the simpler continuous improvement process. But in other contexts where rapid learning is possible, the decision analysis process can be overly cumbersome. Thus both processes have their role in individual decision making (Fig. 2).

Like continuous improvement, decision analysis can be viewed as having four phases:

1. identifying the key deciders with the resources to make or respond to change;

2. having deciders articulate desires for improvements in the system and analyze these desires to identify the underlying values of the deciders;
3. analyzing how different interventions could impact how well the system performs (as measured by decider values) given all the relevant uncertainties; and
4. choosing (and committing to) a plan for intervening in the system.

With some reinterpretation, we can similarly represent decision analysis as a cycle (Fig. 3).

This cycle is useful in highlighting the four key elements of a decision:

1. *Deciders*. Creating a list of deciders that is too small can dramatically limit the decisions that one can feasibly implement and, all too frequently, lead the decision to be blocked or revised by stakeholders who are left out of the decision. Creating a list of deciders that is too large can make the decision-making process too cumbersome. Ideally the list of deciders, as well as the list of issues that are considered within the scope of decision, reflects the proper balance to responsibly, but efficiently, make a decision.
2. *Values*. Explicit enumeration of all the relevant values, including monetary values, safety issues, and impact on the quality of life of all the deciders is critical in guiding our decision. Ignoring critical values or failing to acknowledge trade-offs between certain values (e.g., safety vs. income) can clearly weaken the impact of the decision.
3. *Uncertain States*. Much of decision analysis is focused on the analytical evaluation of the consequences of various choices in various uncertain states. It requires the application of good logic, which—because of the complexity of probability theory—is

Figure 1. Deming cycle.

Figure 2. Perils of both continuous improvement and decision analysis.

often easy to violate. It also requires the collection of quality data—which can be especially onerous in real applications. Fortunately, decision analysis contains mechanisms, often

referred to as *value of information* analysis, which helped identify which data must be gathered and which data need not be gathered.

Figure 3. The decision cycle.

4. *Choices.* Choices are irreversible (and, as the caveman symbolizes, often violent) commitments to change the status quo. The deciders should brainstorm as many choices as possible. At the same time, the Archimedean axiom of decision theory requires that the decider screen out any choice which potentially leads to outcomes that are “infinitely worse” than the outcomes produced by other decisions. Thus the decider must screen out choices that are morally or legally unacceptable.

To ensure that deciders remember these four elements, diamonds are used to symbolize deciders with resources, hearts to symbolize values, spades to symbolize states of uncertainty, and clubs to symbolize choice. Hence any decider familiar with a deck of cards can remember the four elements.

Since failing to make good decisions is, in certain contexts, legally equivalent to negligence, most decision making has a moral dimension. As a result, the characteristics

of good decision making (including Matheson’s six characteristics of effective decision making) are decision “virtues” and are aligned with the classic virtues of justice, temperance, prudence, and courage (Fig. 4).

PROBLEM FRAMING

To ensure that all values relevant to the decision are considered, we draw a means/ends diagram that begins with each value and asks “why is that value important?” Repeatedly answering this question eventually leads us to a fundamental value which can subsume many of the other values that might have been voiced as important. For example, one person might say that money is important for the following reasons:

Making Money

is important because

I can live well;

This is important because

I enjoy physical pleasures.

Another person might say that making money is important for different reasons:

Figure 4. The decision clock.

Making Money

is important because

I can support the environment movement;

This is important because

I want future generations to have a clean world;

This is important because

I value the future of the human race.

Hence the same apparent interest in making money is based on potentially fundamentally different values. The means/ends diagram can also highlight other values that we consider important but failed to articulate. Once values have been identified, we define scales for measuring performance on each value.

We then assess the relevant states and decisions using an influence diagram. An influence diagram begins with a fundamental value and asks the question:

What are the small number of first-level factors which must be specified in order to know how well we performed on the fundamental value?

Once this question is answered, we then focus on each first-level factor and identify the small number of second-level factors required to specify performance on the first-level factor. We continue iteratively until the influence diagram has the requisite detail. In many cases, the analyst may have to completely scrap the influence diagram and draft a different influence diagram that makes different distinctions. *While tedious, making good distinctions is critical to making good decisions.* Since influence diagrams can become very detailed, contemporary influence diagram software like Analytica introduced modularity to allow the influence diagram to decompose into submodels. Analytica also introduced

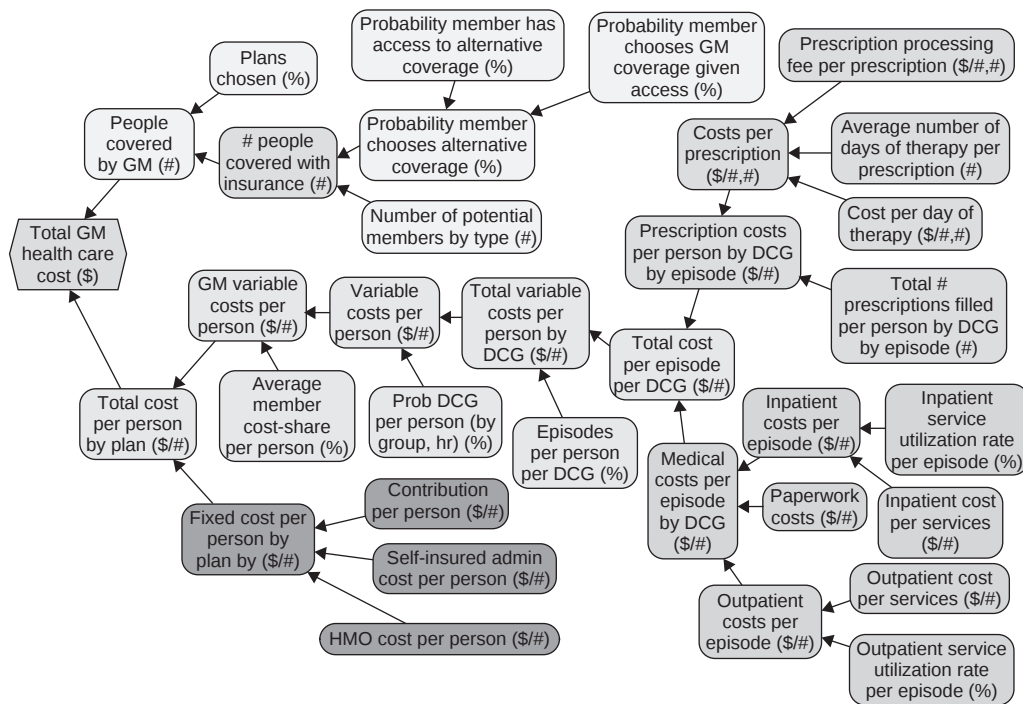

Figure 5. Drivers of health cost.

intelligent arrays that allow the analyst to quickly change the number of dimensions associated with each variable. The factors identified in an influence diagram can then be characterized as either controllable decisions or uncontrollable states. We only focus on those uncontrollable states whose value is unknown to us (uncertainties).

Figure 5 gives an example of an influence diagram focused on health-care costs. We first write health-care costs as a function of total cost per person by the health-care plan multiplied by the number of people covered by the health-care plan. We then write the total costs per person by plan as

a function of the variable costs per person and the fixed cost per person per plan. And we continue expanding in this way until our influence diagram has allowed us to identify possible actions and critical uncertainties in understanding our variable of interest, that is, total health-care costs.

In some contexts, the familiar arc and node representation of influence diagrams—which have sometimes been criticized as “spaghetti diagram”—is confusing. When the influence diagram can be decomposed in a treelike fashion, it is possible to represent it using the following outline representation:

Health Care Costs

People Covered

Plans Chosen

People Covered with Insurance

Number of Potential Members by Type

Probability Member Chooses Alternative Coverage

Probability Member has Access to Alternative Coverage

Probability Member Chooses Alternative Coverage Given Member Access

Total Cost per Person by Plan
 Fixed Cost per Person by Plan
 HMO Cost per Person
 Self-Insured Administration cost per person
 Contribution per Person
 Corporate Variable Costs per Person
 Average Member Cost-Share
 Variable Costs per Person
 Disease Category Probability per Person
 Variable Costs per Disease Category
 Episodes per Person by Disease Category
 Costs per Episode by Disease Category
 Drug Costs per Episode
 No. of Prescriptions per Episode
 Cost per Prescription
 Medical Costs per Episode
 In-patient Medical Costs per Episode
 Out-patient Medical Costs per Episode

The choice between these two representations clearly depends upon the audience. The second representation is less useful when there is one factor that affects several branches of the tree that expands out from the health-care cost node. But the author found the second representation useful with an audience more comfortable with an outline format.

The next critical step is assigning values to the end nodes (or to the lowest level categories in the outline format.) These values may be numbers, matrices, or multidimensional arrays. Once this is done, the relationship between the value assigned to a node and the values assigned to a node with arrows leading into that node (or the value assigned to a higher level category as a function of the values assigned to the lower level categories) must be quantified. This allows one to specify the topmost level (health-care costs) as a function of the lowest level costs. Note that the outline format is readily quantifiable in an MS Excel worksheet.

After quantifying the influence diagram, we specify how much each variable (whether it is a controllable variable or an uncontrollable variable) can be varied. We then typically conduct a Pareto analysis on the variables to identify which variables materially impact the topmost level variable (Fig. 6).

If the variable is an uncontrollable variable—which varies because of chance—then we may seek to gather more information on that variable. If the variable is an uncontrollable variable—which varies because the individual controlling that variable was not involved in our decision making—we may want to consider adding the individual to our group of deciders (the decision board). Alternatively, we may simply choose to treat that uncontrollable variable as an uncertainty.

We then eliminate all the variables that are less important so that we can restrict our focus to those variables, uncontrollable and controllable, that really matter. Thus the influence diagram helps us to determine the deciders, the relevant decisions, and the relevant states of uncertainties that will be included in our decision tree.

DECISION ANALYSIS: THE SIMPLEST CASE

The next step is to assign a time to each decision and uncertainty. The time for an uncertainty is the earliest time at which the outcome of that uncertainty is known to the deciders (or their representative). The time for a decision is the latest time at which that decision can be made without penalty. Thus, suppose you need to make a decision about whether to invest in some startup company.

Figure 6. Cumulative Pareto chart (fake).

After you invest, you learn a few months later whether the company is viable or goes bankrupt. A few months after learning that the company is viable, you then learn how much profit the company makes. Thus the timeline is

Invest → Company Success/Failure?
→ Company Profitability

Note that the attractiveness of this investment opportunity would generally be quite different from the attractiveness of an opportunity where you learned about whether the company would go bankrupt before investing. In this case, the timeline would be

Company Success/Failure → Invest
→ Company Profitability

Note that only the sequence in which decisions are made and uncertainties are resolved is relevant in this ordering. There is no explicit consideration, at this point, of the time lag between investing and company success/failure. Instead, the time lag is implicitly considered in a later stage of evaluating the tree. If there is uncertainty in the time lag, then it is explicitly considered by introducing an uncertainty, “time until a relevant uncertainty is resolved” and treating that uncertainty like any other uncertainty. Thus the standard approach to treating decision trees differs from stochastic decision trees which attempt to represent the uncertainty in these time lags explicitly in the structuring of the tree.

The next step is listing the possible outcomes for each uncertainty and the possible outcomes of each decision. Thus there might be two outcomes for company success/failure, namely success or failure, and there might be two outcomes for company profitability, namely high or low. Finally, there might be two possible choices for each decision, “Invest” or “Don’t Invest.” Since there may be many ways in which the outcomes of an uncertainty could be decomposed, some care is required. Too detailed an elaboration of the possible outcomes of an uncertainty could make the analysis more difficult than necessary. Too limited an elaboration of the possible outcomes of an uncertainty might aggregate two outcomes which have very different characteristics.

This could be done through the visual tree where an uncertainty is represented by a rectangle, with the relative size of the rectangle representing the relative probability of that decision. Thus we might represent the investment problem as in Fig. 7.

In this representation, we represent our choice between either investing or not investing with two arrows, one going to the alternative, *Invest*, and the other going to the alternative, *Don’t invest*. The “Invest” alternative then leads to either “Success” or “Failure,” with the relative sizes of the rectangles indicating that success is more likely than failure. Finally, the “Success” rectangle leads to the “High payoff” and “Low payoff” rectangles. Since these two rectangles have roughly comparable sizes, the chance of high payoff given success is roughly the same as the chance of low payoff given success.

Figure 7. Visual decision tree.

We now need to evaluate the tree. While we constructed the tree beginning with the present and moving forward in time, we evaluate the tree by going to the last consequences and moving backward in time. More specifically, we evaluate the tree by first attaching values to the end consequences of the decision tree.

In order to do so, we first consider the simple case in which we are only interested in whether or not we achieve some consequence (e.g., enough money to retire comfortably.) In this case, the decision tree can be expanded to include the ultimate outcome of interest (Fig. 8).

In color theory, the value of a color is the amount of lightness in that color, with white representing the maximum value and black representing the minimum value. Following this convention, we now shade our endmost nodes by shading the “Retire” rectangle “white” and the “Don’t” rectangle black (Fig. 9).

To see why this is useful, note that the natural value to attach to the “Don’t invest” rectangle is the probability of being able to retire given no investment. The magnitude of this probability is just the color we get by mixing the white in the “Retire” rectangle with the “black” in the “Don’t” rectangle in proportion to the size of these two rectangles. (We can literally think of this as the result of dumping two small cans of white

and black paint to create a single can of an intermediate color.) We can repeat this mixing operation to shade the “Failure” rectangle and the “High payoff” and “Low payoff” rectangles. This gives Fig 10.

We next need to color the “Invest” rectangle. The “Invest” node has a small chance of leading to success, which has an even chance of leading to high payoff (which is almost white indicating that retirement is almost certain given this payoff) and an even chance of leading to low payoff (which is darker indicating a lower chance of achieving retirement given this payoff.) The color of the “Invest” rectangle should be the overall chance of achieving retirement given investment. This can be easily calculated from the adjacent two rectangles of “Success” and “Failure” by mixing their colors (in proportion to the size of the rectangles) as previously discussed. This leads to Fig. 11.

We now face a choice between investing and not investing. The “Invest?” rectangle differs fundamentally from the other rectangles in representing a decision. While the outcome high payoff or low payoff given success was determined by chance, the outcome of the “Invest” rectangle will be determined by choice. Hence we choose the rectangle of highest value, which in this case is not to invest. That rectangle has a dark gray color (while the alternative of investing has a nearly black color).

Figure 8. Visual decision tree with ultimate outcome.

Figure 9. Valuing the end-nodes.

We can now erase the rectangles referring to this ultimate target to get the tree (Fig. 12).

In this problem, we valued the end rectangles in terms of an ultimate target that is either achieved or not achieved. There may also be cases in which there is an ultimate target but—within the

time frame of relevance—we will never eliminate all uncertainty about whether the target is achieved. For example, a physician subscribing to the Hippocratic oath may want to ensure that the life which the patient enjoys after treatment is clearly better than the life which an untreated

Figure 10. Valuing the nodes preceding the end nodes.

Figure 11. Valuing the nodes preceding the nodes in Figure 10.

patient would enjoy. Since the physician clearly cannot foresee the patient's future life, the requirements that the physician must achieve—in order to achieve minimal improvement in the patient's future life—are uncertain. But extending the previous approach to allow for uncertainty about the requirements needed to achieve the physician's target is straightforward.

DECISION ANALYSIS: THE GENERAL CASE

There are, of course, many problems for which there are no well-defined targets. In these cases, decision analysis first identifies the best possible outcome, for example, high payoff, and the worst possible outcome, for example, failure, and assigns them both some value, say, 0.9 and 0.1. (In practice, they are assigned values of

Figure 12. Valuing the remaining nodes.

zero and 1). To attach a value to any intermediate outcome, we ask the decider to imagine an experiment in which he/she must choose between the intermediate outcome and a lottery with some probability p of leading to the best possible outcome (and leading to the worst possible outcome otherwise). Decision analysis assumes there is some value of p for which the decider is indifferent.

To visualize this experiment, we imagine that the intermediate outcome, which we call risk, can lead to either the best possible outcome with this probability (and leads to the worst possible outcome.) As Fig. 13 specifies, this shows that the color we attach to this intermediate outcome is the color we gain by proportionately mixing the colors in the two adjacent rectangles.

This hypothetical experiment is what must be introduced when we cannot assume

that each outcome is ultimately only valued on the basis of whether it helps the decider achieve some fixed target.

Thus the problem of maximizing the probability of achieving the target (or the uncertain target) in the previous section is generalized to the problem of maximizing the expected value of the pseudoprobability (or preference probability) where the preference probability is associated with hypothetical gambles. Since any preference probability can always be interpreted as the probability of achieving some uncertain target (which might be purely hypothetical), one could view the above assessment procedure as a procedure for assessing the probability distribution of a hypothetical, uncertain target. Whether one should use the language of utility or the language of uncertain targets will depend upon which language is more meaningful to the client. In some cases, the

Figure 13. Computing expected utility visually.

notion of utility as some kind of measure of “happiness” will make utility the more natural notion. In other cases where clients are familiar with constraints and target, the language of uncertain targets will be more natural. Whatever the interpretation, this allows us to shade the end rectangles as shown in the tree in Fig. 14.

As previously noted, we proceed backwards in assigning values (or shadings to the end consequences). We assign a color to the success rectangle by mixing the shadings of the adjacent rectangles, high payoff and

low payoff. We then assign a shading to the “Invest” rectangle by mixing the shadings of the newly shaded “Success” rectangle and the “Failure” rectangle (Fig. 15).

As before, we make the decision to invest by choosing the brand of higher value (or lighter color). Thus a decision tree essentially replaces the complex uncertainty associated with any series of decisions by a two-outcome lottery (leading to either the best possible outcome or the worst possible outcome.) Since it is clear how to choose among such two-outcome lotteries (i.e., we always choose that

Figure 14. The visual decision tree with no ultimate outcome.

Figure 15. Valuing the nodes in the tree.

Figure 16. The visual tree with perfect information.

Figure 17. Valuing the visual tree with perfect information.

lottery with the highest probability of yielding the best outcome), this specifies a defensible procedure for decision making.

The order in which we need to make these decisions and resolve these uncertainties remains critical. For example, if we knew whether a successful investment would be high payoff before we made our decision, we would draw the tree as in Fig. 16, which, upon being appropriately shaded would have the form as in Fig. 17.

The fact that the color attached to the “Payoff” rectangle in this case is lighter than the color attached to the “Payoff” rectangle (when we decided before we knew the

outcome of a success investment) indicates that it is better to have this information earlier.

THE NUMERICAL DECISION TREE

The visual decision tree displays all the key elements of decision analysis. But since it uses colors and shapes, it is inherently less precise than a numerical representation since a number can be represented to an arbitrary degree of accuracy. In many problems, the precision implied by a number is misleading and hence the visual representation may be appropriate. But in dealing with low probability, high consequence risks, precision is essential. In such cases, the visual tree (Fig. 18) would be replaced by the numerical decision tree (Fig. 19).

In the numerical decision tree, all shapes have comparable sizes and colors, with numbers under the arcs indicating the probabilities and numbers at the end of each branches (or above the nodes) representing values. In reading this decision tree, we distinguish between decisions and uncertainties by representing decisions with rectangles and uncertainties with ovals. Above the arcs emanating from a decision, we list the decision alternative associated with that arc. Above the arcs emanating from an uncertainty (e.g., outcome), we list the possible outcomes (success, failure) of that uncertainty. Below the arc labeled success, we list the probability of the “success” event occurring—conditioned on all decisions and uncertainties preceding the outcome node occurring. Thus if we move to the arc labeled “Hi”, the probability of 0.5 is conditioned on a successful result from the outcome node and a “Yes” decision to invest. The joint probability of the branch associated with a successful outcome and a high payoff is the product of the probabilities of the arcs making up that brand. Thus the joint probability of a high payoff from a successful outcome given a “Yes” decision to invest is $(0.7) \times (0.5) = 0.35$.

The numbers at the end of each branch (e.g., the 0.4 at the end of the branch emanating from a “No” decision on investing) are

Figure 18. Comparison of the visual tree and the numerical tree.

Figure 19. The numerical decision tree.

the values attached with all the events and decisions along that branch occurring. Thus if we do not invest, then we are indifferent between the outcome of this branch and a lottery offering us a 40% chance of the best possible outcome (and giving us the worst possible outcome otherwise). The value of 1 appearing at the end of the branch associated with a “Yes” on investing; a successful outcome and a high payoff implies that this outcome is the best possible outcome. The value of 0 appearing at the end of the branch associated with a “Yes” on investing, and a failed outcome implies that this outcome is the worst possible outcome. The 0.1 appearing at the end of the branch associated with a “Yes” on investing, a successful outcome, and

a low payoff indicates an outcome less desirable than not investing. (The 0.1 indicates that we are indifferent between that outcome and a 10% chance of the best possible outcome—with the worst possible outcome occurring otherwise.)

After assigning numbers at the end of the branches, we again move backward in the tree and assign values to the adjacent nodes. Instead of coloring the “Payoff” node by mixing colors from “end rectangles,” we compute $0.5 \times 0.1 + 0.5 \times 1 = 0.55$ and place that number above the “Payoff” node. Instead of coloring the outcome node by mixing colors from a “Failure” rectangle and a “Payoff” rectangle, we compute $0.7 \times 0.55 + 0.3(0) = 0.385$ and place that

number above the outcome node. Finally instead of coloring the “Invest” rectangle with the lighter of the two colors of the adjacent rectangles, we write the largest of the two values from the adjacent rectangles, that is, the maximum of 0.385 and 0.4 above the “Invest” rectangle. The value associated with the optimal decision is then 0.4. Hence this opportunity is equivalent to a 40% chance of getting the best possible outcome (investing, succeeding, and getting the high payoff) and a 60% chance of getting the worst possible outcome (investing and failing.)

This more analytical representation can itself be replaced by a more general representation when uncertainties are continuous. In this case, we rewrite the tree in collapsed form as

$$\begin{aligned} \text{Max(Invest)} &\rightarrow E[\text{Outcome}|\text{Invest}] \\ &\rightarrow E[\text{Payoff}|\text{Invest, Outcome}] \end{aligned}$$

where $E[\text{Outcome}|\text{Invest}]$ indicates that we compute the probability-weighted average (or expected value) of our payoff over the possible outcomes given we invest and given we don't invest and where Max(Invest) indicates that we compute the maximum of the value given invest and given we don't invest.

Note that when we learn the payoff of a successful outcome before investing, the tree must be written as

$$\begin{aligned} E[\text{Payoff}] &\rightarrow \text{Max(Invest}|\text{Payoff)} \\ &\rightarrow E[\text{Outcome}|\text{Invest, Payoff}] \end{aligned}$$

Since the individual first learns about the payoff, he/she then makes the investment decision and then learns the outcome of the investment.

In the visual decision tree, we represent the value attached to end points by shades of gray. The shade of gray corresponds to the probability which would make one indifferent between the outcome colored gray and a gamble which has that probability of leading to the best possible outcome (colored white) and which leads to the worst possible outcome (colored black). In the conventional decision tree, we represent the value attached

to end points by numbers. But as with the visual tree, these numbers correspond to the probabilities which would make one indifferent between the current outcome and a gamble which has that probability of leading to the best possible outcome and which leads to the worst possible outcome otherwise. As previously noted, these numbers are called *utilities*.

In many applications, individuals prefer to work with cash values rather than the more abstract notion of utility. Once we ascertain the utility of an opportunity (i.e., the value of Max(Invest)), this can be computed by simply finding that cash value which has the same utility as Max(Invest) from the tree:

$$\begin{aligned} \text{Max(Invest)} &\rightarrow E[\text{Outcome}|\text{Invest}] \\ &\rightarrow E[\text{Payoff}|\text{Invest, Outcome}] \end{aligned}$$

If we are asked to compute the value of information on the payoff, then we would first solve the revised tree which assumes we know the payoff before making a decision:

$$\begin{aligned} E[\text{Payoff}] &\rightarrow \text{Max(Invest}|\text{Payoff)} \\ &\rightarrow E[\text{Outcome}|\text{Invest, Payoff}] \end{aligned}$$

We would then find the cash value which has the same utility as $E[\text{Payoff}]$. Finally, we compute the value of information on payoff as the difference between the cash value of $E[\text{Payoff}]$ and the cash value of Max(Invest) . This is the amount by which having information on the payoff before we make the decision has increased the cash value of the opportunity.

While decision trees represent all quantities in terms of lotteries giving rise to either the best outcome or the worst outcome, it is common to try to approximate them with decision trees that work in terms of deterministic quantities, for example, cash values. (In target-oriented utility theory, this corresponds to assuming that the individual wishes his wealth to exceed a uniformly distributed random variable.) In this approximation, we replace all utility values by cash values. Thus we begin by assigning cash values to the end points of the tree (Fig. 20).

Figure 20. Expected value with the numerical tree.

We then do the same calculations using cash values as we would with utility values.

Thus the value assigned to the “Payoff” node is the probability-weighted average of \$50 and \$1000, or \$525. The value attached to the outcome node is the probability-weighted average of \$525 and 0, or \$367.50. The value attached to the “Invest” node is the maximum of \$367.50 and 0, or \$367.50. Note that in this tree we choose to invest, whereas in the tree with utilities we chose not to invest. This highlights the fact that the expected cash value rule is only a heuristic which is sometimes a good approximation for the result that would be achieved using the utility rule. One way of measuring the error in the approximation is by examining the difference between the cash value associated with $\text{Max}(\text{Invest})$ from the tree with utilities and the cash value associated with the tree using expected cash values. This is called the *risk premium*. An individual for whom the risk premium is zero, that is, for whom the expected cash value rule always gives the same results as the exact expected utility rule, is said to be risk neutral. In this case, utility is proportional to the cash value.

The expected cash value rule is also an excellent rule for decision trees applied to evaluating stock market derivatives (as well as for real options not directly connected to the stock market decisions). In these cases,

the probability associated with a given uncertainty (described by a security in the stock market) must be replaced by a risk-neutral probability. This risk-neutral probability is defined in terms of the values attached to derivatives and the underlying securities and has no relationship to the actual chance of the event occurring. Nonetheless, with these risk-neutral probabilities, maximization of the expected cash values can be fully justified.

CONCLUSIONS

The decision tree is an excellent tool for reducing complicated problems involving considerable uncertainty to more transparent choices between simpler gambles. Our review of decision trees differed from traditional reviews of decision trees in three ways:

1. *Explicit Comparison with Continuous Improvement.* Since decision analysis is designed for addressing strategic (and not operational) decisions, this article goes into more detail on Deming’s process as an operational alternative.
2. *Targets as the Simplest Case.* Traditional courses on decision analysis begin by teaching the rule of maximizing expected cash value, then telling students the rule is flawed, and then

teaching expected utility maximization. As an alternative, this article begins with maximizing the chance of achieving a target—a decision criterion already widely understood—and then introduces the expected utility criterion to describe cases where targets are not well defined. This also makes it easier to describe the rationality assumptions underlying decision theory (if desired). The expected value criterion is introduced last as a critical special case.

3. *Visual versus Numerical Representation.* Many clients cannot handle numbers or believe that using numbers requires precision. In response, this article begins with visual decision tree representation (where great precision is not possible) and transitions to numerical representations which allows for great precision.

Hence this article provides a rigorous but user-friendly perspective on decision trees.

DESCRIPTION OF THE FRENCH OPERATIONAL RESEARCH AND DECISION-AID SOCIETY: *SOCIÉTÉ FRANÇAISE DE RECHERCHE OPÉRATIONNELLE ET D'AIDE À LA DÉCISION* (ROADEF)

OLIVIER HUDRY
École nationale supérieure
des télécommunications,
Paris, France

PRESENTATION OF THE ROADEF

Formed in 1998, the *Société française de recherche opérationnelle et d'aide à la décision* (ROADEF; <http://www.roadef.org>) is the French society of operational research (OR) and decision-aid. It is a member of the *Association of European Operational Research Societies* (EURO), itself within the *International Federation of Operational Research Societies* (IFORS). The ROADEF aims to promote, in France, all the activities related to the OR and the decision-aid in all possible fields such as teaching, research, industries, civil and military applications, and so on. In this respect, the ROADEF carries on the work of the *Association française pour la cybernétique économique et technique* (AFCET). Founded in 1968 by the merging of four previous scientific associations, the AFCET was the main association dealing with computer science and information theory during the 1970s and the 1980s. The AFCET gathered several groups; one of them was devoted to OR.

In 1998, while the AFCET disappeared, 20 founder members created the ROADEF.

- Some of them were individuals such as Denis Bouyssou (ESSEC), Jacques Carlier (Université technologique de Compiègne), Philippe Chrétienne (Université Paris VI), Stéphane Dauzère-Pérès (École des

Mines de Nantes), Dominique Fortin (INRIA), Xavier Gandibleux (Université de Valenciennes), Nelson Maculan (Universidade Federal do Rio de Janeiro), Ali Ridha Mahjoub (Université Clermont-Ferrand II), Gérard Plateau (Université de Paris-Nord), Jean-Charles Pomerol (Université Paris VI), Marie-Claude Portmann (Institut national polytechnique de Lorraine), Christian Proust (Université de Tours), Catherine Roucairol (Université de Versailles), and Bernard Roy (Université de Paris-Dauphine).

- The others were legal (industrial or academic) entities such as Bouygues, Euro-Décision Technologies, Gaz de France, LAMIH/ROAD (Université de Valenciennes), LAMSADE (Université de Paris-Dauphine), and SNCF.

After a period of about 10 years, the ROADEF has gathered between 300 and 400 members (390 in 2009), from universities or industrial companies. Members can be researchers, engineers, Ph. D students (64 in 2009), retired persons (3 in 2009), institutions or companies. We should also mention two honorary members—Bernard Roy and Marie-Claude Portmann—for their great involvement in OR or in the life of the ROADEF.

THE SUCCESSIVE BOARDS OF THE ROADEF

Marie-Claude Portmann was the first president of the ROADEF. More precisely, the board of the ROADEF has six members, elected by the other members of the ROADEF for 2 years, with at most two mandates: one president (P), three vice presidents (VP), one secretary (S), and one treasurer (T). From the birth of the ROADEF, the boards were composed of the following:

- 1998–1999: Marie-Claude Portmann (P), Alix Munier (S), Laura Wynter (T),

Jean-Robert Leroy (VP), Xavier Gandibleux (VP), and Alexis Tsoukias (VP);

- 2000–2001: Denis Bouyssou (P), Alix Munier (S), Ariane Partouche (T), Stéphane Dauzère-Pérès (VP), Xavier Gandibleux (VP), and Jean-Robert Leroy (VP);
- 2002–2003: Arnaud Fréville (P), Marie-Christine Costa (S), Éric Gourdin (T), Philippe Baptiste (VP), Van-Dat Cung (VP), and Anass Nagih (VP);
- 2004–2005: Marie-Christine Costa (P), Jean-Charles Billaut (S), David de Almeida (T), Christian Artigues (VP), Safia Kedad-Sidhoum (VP), and Éric Sanlaville (VP);
- 2006–2007: Jean-Charles Billaut (P), Clarisse Dhaenens-Flipo (S), David de Almeida (T), Safia Kedad-Sidhoum (VP), Éric Sanlaville (VP), and Mohamed Ali Aloulou (VP);
- 2008–2009: Olivier Hudry (P), Clarisse Dhaenens-Flipo (S), Denis Montaut (T), Christelle Guéret-Jussien (VP), Francis Sourd (VP), and Mohamed Ali Aloulou (VP).
- The board for 2010 and 2011 will be Francis Sourd (P), Nadia Brauner (S), Denis Montaut (T), Christelle Guéret-Jussien (VP), Nathalie Sauer (VP), and François Vanderbeck (VP). Moreover, Éric Pinson will be in charge of the communication and promotion of OR in the view of the different partners of the ROADEF such as authorities, industrial companies, universities, research laboratories, and so on.

ANNUAL NATIONAL MEETINGS OF THE ROADEF

The ROADEF organizes a national meeting every year, in different places such as Paris (1998, 2002), Autrans (1999), Nantes (2000), Avignon (2003), Tours (2005), Lille (2006), Grenoble (2007), Clermont-Ferrand (2008), Nancy (2009), and Toulouse (2010). These meetings gather about 300 participants (for

instance, there were 320 participants in Nancy with 198 communications). A book of selected contributions involving students as authors or coauthors is published by the organizers and distributed to all the participants, as well as a booklet of all the abstracts. Since 2002, a selection of articles has been published after the meeting as a special issue of a journal, *Mathematics and Social Sciences* in 2002 (with I. Charon and O. Hudry as the invited editors), *RAIRO-Operations Research* for the meetings from 2002 to 2008 (with the following invited editors: I. Charon and O. Hudry in 2002; C. Artigues, D. Feillet, and P. Michelon in 2003; J.-C. Billaut and E. Néron in 2005; L. Brotcorne, C. Dhaenens, S. Hanafi, and T. El-Ghazali in 2006; C. Artigues, V.-D. Cung, G. Finke, and B. Penz in 2007; P. Mahey and A. Quilliot in 2008), the *European Journal of Industrial Engineering* for the meeting of 2009 (with A. Oulamara and M.-C. Portmann as the invited editors).

WORKING GROUPS OF THE ROADEF

The ROADEF organizes thematic workshops also, devoted to some specific subjects. They are often, though not always, linked to the activities of the working groups of the ROADEF. Indeed, the ROADEF supports several working groups, more or less linked to the ROADEF, including some regional groups. In 2009, these groups are devoted to the following subjects:

- combinatorial optimization (in collaboration with the European Chapter on Combinatorial Optimization—ECCO);
- complex systems and distributed decisions (in collaboration with the working group Modelisation, Analysis, Management of Dynamic Systems of the French National Centre of Scientific Research—CNRS);
- constraints and OR (in collaboration with the French Association for Programming by Constraints);
- knapsack and optimization;
- mathematics of optimization and decisions (in collaboration with the

working group Mathematics of Optimization and Decisions of the French Society of Industrial and Applied Mathematics—SMAI);

- multicriteria decision aiding (in collaboration with the EURO working group Multicriteria Decision Aiding);
- multiobjective mathematical programming (in collaboration with the working group Information–Interaction–Intelligence of the CNRS);
- OR in the Loire region;
- OR in the Paris region;
- OR in the north-east (gathering teams of the universities of Liège, Luxembourg, Metz, Nancy, Sarrebruck, and Trier);
- optimization in networks (in collaboration with the working group OR of the CNRS);
- parallel processing in OR (in collaboration with the EURO working group Parallel Processing in OR);
- polyhedron and combinatorial optimization (in collaboration with the working group OR of the CNRS);
- scheduling (in collaboration with the working group Modelisation, Analysis, Management of Dynamic Systems, and with the working group OR of the CNRS);
- supply chain and logistics (in collaboration with the working group OR of the CNRS);
- theory and applications of metaheuristics (in collaboration with the working group Modelisation, Analysis, Management of Dynamic Systems, with the working group Mathematical Computer Science of the CNRS, and with the European Chapter on Metaheuristics).

PUBLICATIONS INVOLVING THE ROADEF

The ROADEF is involved in the publication of two international journals such as *4OR*, a *Quarterly Journal of Operations Research*

(<http://homepages.vub.ac.be/~fouror/>) and *RAIRO-Operations Research* (<http://www.rairo-ro.org/>).

The journal *4OR* was founded in 2002 by the OR societies of Belgium (ORBEL/Sogesci-B.V.W.B; <http://www.orbel.be>), France (ROADEF), and Italy (AIRO; <http://www.airo.org/>). Its editors-in-chief were D. Bouys-sou (replaced by P. Baptiste in 2009), S. Martello (still editor-in-chief), and F. Plastria (replaced by T. Marchant in 2010). Its creation was accompanied by the disappearance of the former journals of the Belgian OR society (*JORBEL*) and of the Italian OR society (*Ricerca Operativa*).

The journal *RAIRO-Operations Research* was founded in the 1960s. It is devoted to high-level pure and applied research on all aspects of OR. Its current editor-in-chief is P. Mahey, assisted by five associate editors (A. Billionnet, A. Brandwajn, P. Chrétienne, M. Gendreau, and C. Gonzaga). The ROADEF and the SMAI are the scientific advisors of the journal.

Besides these two journals, the ROADEF also publishes a newsletter and a bulletin. The newsletter, edited electronically by one of the vice-presidents (C. Dhaenens-Flipo in 2009, N. Brauner in 2010), provides brief announcements as news about the association, new books, new conferences, and so on. It typically contains about three pages and is sent to the ROADEF's members, every second month. The bulletin, edited by another vice president (C. Guéret-Jussien in 2009, as well as in 2010) aims at providing a framework for discussions and exchanges inside the OR community, with two issues per year. Each issue typically contains between 20 and 30 pages, usually with an editorial describing the OR activities of an academic or industrial team, an invited scientific article (for instance, in December 2009, this article was written by G. Cornuéjols, on the occasion of his Dantzig prize), reports of some events, scientific or educational notes, as well as various contributions dealing with the activities of the ROADEF's working groups, with the conferences on OR, and more generally with any activity or event related to the ROADEF or OR.

ROBERT FAURE PRIZE

The ROADEF also sponsors the *Robert Faure Prize*, which existed even before the creation of the ROADEF (the first awards go back to 1993). Robert Faure was a professor of OR at the *Conservatoire national des arts et métiers* in Paris, where he held the chair of OR, a unique one in France. This prize is awarded every three years to three (sometimes four) young researchers for their original contributions to OR, especially for work combining theoretical developments and applications [see <http://www.roadef.org/content/roadef/rfaure.htm> for the list of the laureates; several of them became members of the board of the ROADEF: É. Pinson (1993), S. Dautère-Pérès (1996), P. Baptiste (1999), N. Sauer (1999), N. Brauner (2009), and F. Sourd (2003)].

CHALLENGES ORGANIZED BY THE ROADEF

Among the other achievements of the ROADEF, we should mention the “challenge”. The challenge is based on a subject proposed by an industrial or by a public or private institution. For instance, the subject of the 2010 issue is defined by *Électricité de France*; it deals with a large-scale production management problem with varied constraints. Then, different teams study the problem and design methods to solve the problem. There are two categories for the teams: junior and senior. The proposed methods are tested on benchmarks, which allow ranking of the teams and choosing the

winners according to the category (see the website of the ROADEF for the list of the winners). For the first time, in 2010, there will be a prize dedicated to parallel computing methods. Thanks to the success of the previous six challenges (in 1999, 2001, 2003, 2005, 2007, and 2009), the 2010 challenge is jointly organized with EURO. The finalists will be revealed during the ROADEF meeting at Toulouse, while the results will be announced and the winners will be awarded during EURO XXIV, in Lisbon.

The challenge is open to everyone, and particularly to young researchers, excluding people professionally involved with the industrial partners. The aims of the ROADEF’s challenges are multiple: They allow the industrial partners to witness recent developments in the field of OR. In the junior category, young researchers have the opportunity to face a complex optimization problem occurring in industry with its manifold constraints; the challenge gives them an opportunity to explore the requirements and difficulties encountered in industrial applications. In the senior category, the challenges allow qualified researchers to share their knowledge and know-how on practical problems. Moreover, the challenges help to establish or maintain a permanent partnership between industrials and researchers on industrial size projects requiring scientific and practical abilities.

Van-Dat Cung was the organizer of the first five challenges, between 1999 and 2007. He has been replaced by Murat Afsar, Christian Artigues, Éric Bourreau, and Olivier Briant for the 2009 challenge.

DESCRIPTIVE MODELS OF DECISION MAKING

WHY BEHAVIORAL DECISION THEORY?

Decision theory builds on the premise that subjects seek and organize the information available to make a decision in a rational way. Rational here mean “according to a set of appealing principles.” The implications of and relationships between these principles are the area of study of decision theory. The objective of the field of decision theory and analysis is to propose decision rules and processes that might be used in practice to produce more informed and rational decisions. For instance, rational preferences have the property that decision makers are always able to produce consistent rankings of all alternatives. Thus, they are able to associate a utility score to each consequence, and choose the alternative yielding the highest utility. In the face of uncertainty, rational decision makers will calculate the average utility weighted by the subjective probabilities attached to the possible consequences. They will then choose the alternative that yields the highest expected utility.

In the rational model, the evaluation of the consequences and the estimation of probabilities are invariant to the way the consequences and the events are described, or the method employed to elicit these utilities and probabilities. Further, rational preferences are supposed to be dynamically consistent: the partial resolution of uncertainty or the

passage of time does not change the desirability of the residual alternatives. Moreover, factors such as the inclusion or not of past costs should be irrelevant for the decision at hand; only the future consequences matter. Finally, the quality of a decision is to be judged using the information available at the moment of the decision, and a bad outcome might not necessarily be associated to a bad decision. These principles are supposed to be *normative*, because any rational decision maker would follow them.

Common sense indicates that, for complex decisions, subjects might be incapable of producing rational decisions. Ultimately, we have limited capacity to process information. Complexity may arise due to the multiplicity of alternatives, uncertainties, or objectives. Precisely in complex problems is where the role of decision analysis is preeminent. In complex problems, the decision analyst will suggest to separate the problem in its basic elements (objectives, alternatives, uncertainties, consequences), elicit the utilities and probabilities, and then combine these elements to manufacture a decision that mimics that of a rational decision maker. Decision trees to clarify the interplay between uncertainties and alternatives, Monte Carlo techniques to simulate multiplicity of risks, or optimization methods to handle multiplicity of alternatives are part of the toolbox of decision analysis. Hence, decision theory has a *prescriptive* value because it helps decision makers create rational decisions in complex problems.

However, one fundamental question needs to be addressed before this program can be successfully implemented: do people want to behave rationally? The answer to this question seems so obvious, that for a long time the question was not even formulated. The assumption was that people would behave rationally in simple decisions, and the challenge was to extend this rationality to complex decisions. But what if subjects do not want to behave rationally even in simple problems? Then, these subjects will not

seek the aid of decision analysis for complex decisions, as they would feel that acting rationally runs against their preferences.

Behavioral decision theory (BDT) seeks to understand better the irrationalities of subjects. One clear objective of this program is to help subjects convince themselves that acting rationally is better [1,2]. Another objective is to propose *descriptive* utility models that are parsimonious and as predictive as possible of people's behavior. These models can be helpful in the fields of economics and the social sciences. For example, often decisions are not games against nature, but against a quasi-rational agent. We want to understand this quasi-irrational agent in order to set more accurate probabilities in the chance nodes. BDT is considered as one of the three pillars of decision analysis (the other two being the normative and the prescriptive pillars).

Often BDT uncovers irrationalities. But on occasions it may broaden our views on rationality and help the normative branch of decision analysis. For instance, descriptive deviations from rationality may reveal that the "real" consequences subjects care for are not what the naïve rational model proposes. For instance, habit formation models [3] together with lending and borrowing constraints justifies the rationality of preference for increasing sequences of income [4] (increasing consumption is the optimal pattern in a model with habit formation).

Finally, in nonmonetary decisions under certainty, the only rule of rationality is to predict as accurately as possible the experienced utility of each consequence [5]. BDT is also interested in developing predictive models of experienced utility. These models might outperform the predictions of subjects, and therefore gain immediate prescriptive status.

Rather than providing an extensive survey of the field, the aim of this article is to introduce the main findings of BDT. We utilize a very simple setup to illustrate what separates behavioral preferences from rational preferences. Specifically, we examine choices over prospects of the following form: receiving outcome x with a probability p at time t , and zero otherwise. The vector (x, p, t) will denote such a typical prospect. In the section

titled "Decisions under Risk and over Time: The Rational Model," we present the preferences of the rational decision maker, while in section titled "Decisions under Risk and over Time: The Behavioral Model," we contrast it with the preferences of the modal subject that we observe in experiments. In these two sections the focus is on how decision makers should or would treat probability and time. There, the probability p is objectively given, and we set x to some simple object, such as amount of money, or some quantity of a consumption good. Unless stated otherwise, x will be a gain or positive reward.

In the section titled "Estimating Subjective Probability" we consider the subjective estimation of p . Rather than risk (given objective probabilities), subjects face uncertainty. We show multiple biases in the estimation of probabilities.

Finally, in the section titled "Facing Trade-Offs," where we focus on multi-attribute consequences, x will be a vector encoding a potentially rich set of attributes of the consequence. This section also illustrates the different approaches to the behavioral study of decision making: rather than a behavioral utility model of *preferences*, presented in the first part, the approach is to model *process* that people follow to make complex decisions. While the approach in the sections "Decisions under Risk and over Time: The Rational Model" and "Decisions under Risk and over Time: The Behavioral Model" considers the trade-offs subjects might be making, the approach in the section titled "Facing Trade-Offs" considers procedures that subjects might follow precisely to avoid making trade-offs!

DECISIONS UNDER RISK AND OVER TIME: THE RATIONAL MODEL

How would a rational decision maker decide in simple problems involving risk and time? To begin with, such a decision maker would hold a preference over pairs of prospects that is complete, transitive, and (arguably) continuous. This condition holds if and only if there is a continuous function $V(x, p, t)$ that scores prospects according to preference. Additional conditions on preferences

will then impose constraints on the shape of V . One such constraint is monotonicity, which makes V increasing in x and p , and decreasing in t (impatience). What other constraints can we impose on V in the name of rationality?

V is Linear in Probability

Assume we start flipping a fair coin. Contemplate the prospect of gaining \$1000 if the coin lands on heads the next *five* times, and zero otherwise. How would you compare this offer with the prospect of gaining \$500 if the coin lands on heads the next *four* times, and zero otherwise? In other words, Choice #1 is as follows:

	Prospect A	Prospect B
#1	(\$1000, $1/2^5$, now)	(\$500, $1/2^4$, now)

The expected value of both outcomes is the same. Let us suppose our preference for risk leads us to choose A as we see the rewards of \$1000 more appealing. So far, there is nothing wrong with our preference. As we start flipping the coin, the original prospects in #1 change. For instance, if the coin lands tails the first time, then the residual prospects A_T and B_T are both zero. But, what if the coin lands heads the next four times? Then, the residual prospects are

	Prospect A_{4H}	Prospect B_{4H}
#2	(\$1000, $1/2$, now)	(\$500, for sure, now)

Given a choice between \$500 for sure and a 50% chance of \$1000, we may prefer B_{4H} , the sure thing. Somehow, as the coin lands on heads, we have shifted our preference toward the \$500 reward (B_{4H} in #2), eventually reversing our original preference for the \$1000 reward (A in #1). Is this rational? Arguably, this preference reversal is not rational because it is clear from the beginning that either reward is available only if

the first four flips land on heads. Why should we change our mind if we observe four flips that land on heads? This reversal implies that, from a distance, we pay more attention to outcome size. When the possibilities are closer, then we become more sensitive to probabilities. This cannot be a good way to make a decision, because it shows the lack of clarity in the objective one is trying to reach. It is better to choose either A or B and stay with the choice.

Ruling out this type of reversals is the essence of the independence axiom, proposed by Von-Neumann and Morgenstern [6] and broadly discussed in the literature. In a general setup, this reversal will not occur if and only if the function V is linear in the probability p ,¹ that is, $V(x, p, t) = pg(x, t)$, for some function $g(\cdot)$.

V is Exponential in Time

Consider Choice #3, involving a sure gain of \$1000 in 5 years from now, or a sure gain of \$500 in four years from now.

	Prospect A_{4H}	Prospect B_{4H}
#3	(\$1000, for sure, 5 years)	(\$500, for sure, 4 years)

We are patient, and prefer A. Assume the rewards are fixed to some calendar date. This means that, as time passes, the prospects in

¹The “only if” statement holds in the case of multiple-outcome lotteries, or in the case of simple lotteries if we add a *double cancellation* condition [7] that makes V a multiplicative separable function of p and x , that is, $V(x, p) = w(p)v(x)$. The no reversal condition implies $v(y)/v(x) = w(p)/w(q) = w(\lambda p)/w(\lambda q)$. Fixing q and letting $w(\lambda q)/w(q)$ be a function $g(\lambda)$ of λ , we have $w(\lambda p) = g(\lambda)w(p)$. The unique solution to this Pexider equation is $w(p) = bp^c$ [8]. But in the same way that the multiple-outcome utility is unique up to affine transformation, in the simple lottery case $\ln(V)$ is unique up to affine transformation, which means that we can normalize so that $w(p) = p$.

#3 change and get closer. In fact, 4 years later, the residual prospects are

	Prospect A_{4Y}	Prospect B_{4Y}
#4	(\$1000, for sure, 1 year)	(\$500, for sure, now)

Suppose we now become impatient, and prefer B_{4Y} .² Is the choice pattern A in #3 and B_{4Y} in #4 rational? Arguably not, because it is clear from the beginning that time will pass, and why should we change our mind as time passes? Preference reversals due to lack of stationarity are expected to be frequent, as the passage of time affects all our decisions. The condition that rules out these preference reversals is called the *stationarity axiom*. In a general setup, this type of reversal is ruled out if and only if the function V is exponential in the delay t . To recapitulate, the rational model will look as follows:

$$V(x, p, t) = pe^{-rt}v(x) = \frac{v(x)}{e^{\ln(1/p)+rt}} \quad (1)$$

where $v(x)$ is any increasing function. Note the unorthodox presentation; we write $p = 1/e^z$, where $z = \ln(1/p)$ is a measure of *risk distance*. Suppose the coin we used in Choice #1 had probability $1/e$ of landing heads. A reward that depends on the coin landing heads in the first z flips is at a risk distance of z . Zero distance corresponds to $p = 1$; distance one corresponds to $p = 1/e = 37\%$; distance two to $p = 1/e^2 = 14\%$; distance 3 to $p = 1/e^3 = 5\%$; and infinite distance to $p = 0$.

The parameter r is known as the *discount rate*. The discount rate reflects time preference and impatience: to which extent a larger later reward shall be preferred to a smaller sooner reward. However, in Equation (1) the parameter r has a second, very different interpretation, namely, *the trade-off rate*

²In experimental studies, we rarely make subjects wait for four years and ask them the question. We present Choice #4 now, and assume that the preference for the immediate reward would hold both for now and four years.

between risk distance and time distance. For instance, delaying the reception of a reward by one period is equivalent to a probability reduction of e^r . Or, multiplying the probability of receiving the reward by a factor of λ is equivalent to delaying its reception by $\ln(1^\lambda)/r$ time units. When interpreted this second way, r will be called the *probabilistic discount rate*.

No Reference Dependence

Consider the function v in Equation (1). Does rationality imposes further restrictions on v ? Recall Choice #2 between (\$1000, $1/2$, now) and (\$500, for sure, now), and our preference for the sure \$500. Suppose that we want to meet the target of making a profit of \$1000. This could be because we want to recover a recent loss of \$1000, or match the earnings of some friend to avoid envy. Relative to our target, a gain of \$1000 is neutral, and receiving zero becomes a loss of \$1000. Choice #2 is then perceived as

	Prospect $A_{4H-\$1000}$	Prospect $B_{4H-\$1000}$
#5	(-\$1000, $1/2$, now)	(-\$500, for sure, now)

Suppose we choose $A_{4H-\$1000}$. Is the pattern B_{4H} in #2 and $A_{4H-\$1000}$ in #5 rational? It is clearly irrational, because the alternatives in #2 and #5 are actually the same! All that changes is the description and perception of the same consequences. The change of perception is the consequence of comparing the same consequence to a different reference point. Changing the reference point is equivalent to adding or subtracting a common quantity from all the consequences. This change might be quite common, for example, by including past or future committed costs, or by adding existing balances of money or asset values, or by expressing the consequence relative to some target. Imposing that preferences should not change based on these reference changes leads to two possibilities:

1. The classical proposal is to set $v(x)$ equal to $u(x + a) - u(a)$, where u is a

stable utility function defined over final wealth positions and a is the wealth prior to the decision. This step will undo the effect of changes in references because the correct calculation of a provides an absolute reference. This yields the expected utility model, the benchmark of rationality:

$$V(x, p, t) = \frac{u(x + a) - u(a)}{e^{\ln(1/p) + rt}}. \quad (2)$$

2. In prescriptive applications, neither u nor a are known, and it is often difficult or artificial to elicit them. Therefore, a more practical possibility is to adopt a functional form for v that is invariant to common additive changes in the payoffs. As it is well known, only the linear form, $v(x) = x$, or the exponential form, $v(x) = 1 - e^{-x/\rho}$, will satisfy this invariance condition.³ The linear and the exponential model also satisfies other desirable properties such as the one switch property of Bell [9], and are mathematically very tractable for applications of expected utility.⁴ Taking this second possibility, the rational model becomes

$$V(x, p, t) = \frac{1 - e^{-x/\rho}}{e^{\ln(1/p) + rt}}. \quad (3)$$

Adopting the second approach, a rational decision maker is characterized by two preference parameters, ρ and r . The additional constraint of risk aversion implies that ρ is strictly positive. The limiting case of ρ equals to infinity correspond to risk neutral preferences, $v(x) = x$.

³If the consequences are evaluated multiplicatively with respect to some reference, say individual income over average income, then the only utility function that is invariant to multiplicative changes in references is the power form, $v(x) = x^\alpha$.

⁴Exponential utility combined with a normal probability distributions yields a mean-variance framework for risk analysis, important in finance. If utility is exponential, then the problem of timing of resolution of uncertainty has an explicit recursive solution [10].

The extension of the rational model to multiple outcomes leads to expected utility: V is the sum-product of utilities and probabilities. In the case of receipts of cash flows over time, the rational approach is to first take the net present values of these cash flows, and then calculate the expected utility of the net present value [11]. In the case of receipts consumption flows, one possible approach is to first take the utility of this consumption, and then discount the utility [12]. However, it might be appropriate to modify the discounted utility model to account for habit formation [3] or satiation [13].

DECISIONS UNDER RISK AND OVER TIME: THE BEHAVIORAL MODEL

Are subjects rational? For a long time it was assumed that, for relatively simple problems, most subjects were to decide rationally. But years of laboratory experiments and field data demonstrate that most subjects exhibit the type of reversals that we just classified as irrational [14–16]. But if Equation (2) or (3) does not describe subjects' preferences, what is the form that V takes?⁵ We answer this question using the mainstream behavioral

⁵One may even question if subjects preferences can be described by a function V . Lichtenstein and Slovic [17] show that, varying the elicitation method, subjects violate the most basic tenant of rationality: if A is strictly preferred to B , then B cannot be strictly preferred to A . Here is the example: most subjects prefer the prospect (\$6, 80%, now) to (\$50, 10%, now). This is their answer in a *choice* question. But when asked for the certainty equivalents (the sure amount that would make them indifferent to the prospect), they report that the certainty equivalent for (\$50, 10%, now) is higher than the certainty equivalent for (\$6, 80%, now). This is their answer in a *matching* question. Given this difference, most researchers in behavioral decision making adopt choice questions to elicit preferences. Matching is replaced by the bisection method, which proposes a sequence of choice questions that ultimately make the two prospects close to indifferent. All evidence we present in this article is obtained using choice questions.

models in decisions under risk and over time [18,19].

Sensitivity to Risk and Time Distance

In the rational model subjects are supposed to possess constant sensitivity to risk and time distance. That is, adding an additional

flip of the coin in Choice #1 or a common delay in Choice #3 should not alter the relative desirability of the prospects. Do subjects exhibit constant sensitivity to risk and time distance? Consider the following experimental evidence:

	Prospect A	Prospect B	Response	N
#6	(€ 9, for sure, now)	(€ 12, with 80%, now)	58% vs 42%	142
#7	(€ 9, with 10%, now)	(€ 12, with 8%, now)	22% vs 78%	65
#8	(100 fl, for sure, now)	(110 fl, for sure, 4 weeks)	82% vs 18%	60
#9	(100 fl, for sure, 26 weeks)	(110 fl, for sure, 30 weeks)	37% vs 63%	60

Let us compare Choices #6 and #7. Choice #6 captures the trade-off between selecting a larger outcome but with lower probability. Choice #7 is constructed from Choice #6, after multiplying all probabilities by a common factor. If preferences were linear in probabilities, then the multiplication of probabilities by a common factor should not change. However, most subjects switch, a reversal known as the *common ratio effect*. Let us compare Choices #8 and #9. Choice #8 shows the trade-off of receiving a larger outcome but later in time. Choice #9 is constructed from Choice #8, after adding a common delay to both prospects. Most subjects switch and want the later larger outcome, a reversal known as the *common difference effect*.

The common ratio and the common difference effects reveal that subjects exhibit

diminishing sensitivity to risk and time distance, respectively. That is, they notice the difference between $z = 0$ (100%) and $z = 0.2$ (80%) in Choice #6 more than the difference between $z = 2.3$ (10%) and $z = 2.3 + 0.2$ (8%) in Choice #7. And they feel the difference between now and one month (#8) more than the difference between 26 and 30 weeks (#9).

An obvious modification of the rational model is to introduce a concave function, $d(z)$, which we could call the *psychological distance function*, or *pdf*. The *pdf* captures the diminishing sensitivity toward risk and time distance. Is the psychological distance function for risk the same as the one for time? To answer this, compare Choices #6 with #10 and #8 with #11.

	Prospect A	Prospect B	Response	N
#6	(€ 9, for sure, now)	(€ 12, with 80%, now)	58% vs 42%	142
#10	(€ 9, for sure, 3 months)	(€ 12, with 80%, 3 months)	43% vs 57%	221
#8	(100 fl, for sure, now)	(110 fl, for sure, 4 weeks)	82% vs 18%	60
#11	(100 fl, with 50%, now)	(110 fl, with 50%, 4 weeks)	39% vs 61%	100

Choice #10 is constructed from #6, after adding a common delay. What we observe is that this common delay produces the same reversal toward the larger outcome, “as if”

time were probability. Similarly, Choice #11 is constructed from #8, but this time after multiplying probabilities by a common factor. This common factor produces the same

reversal toward the larger outcome, “as if” probability were time.⁶

Following Ref. 20, we propose that risk distance can be exchanged with time distance at a rate r . We call r the *probabilistic discount rate*, because this is how fast time makes the outcome disappear as if it were a probability. Formally, we propose the following behavioral model:

$$V(x, p, t) = \frac{v(x)}{e^{d(\ln(1/p) + rt)}}, \quad (4)$$

where d is a concave function. The more concave the d is, the more we depart from

the rational benchmark. The concavity of d is intuitive. In the same way that subjects exhibit diminishing sensitivity to outcomes (a windfall of \$10,000 feels better than an additional \$10,000 added to a windfall of \$100,000), subjects also experience diminishing sensitivity to risk and time distance. A delay of hour feels longer than a delay of one hour added to a four hour delay; and moving from certainty to a probability of 50% feels stronger than a reduction of the probability by 50% when the base probability is 10%, therefore leading to a 5% probability.

Is the probabilistic discount rate r constant? Consider the following two choices.

	Prospect A	Prospect B	Response	N
#12	(€ 5, with 90%, now)	(€ 5, for sure, 1 month)	57% vs 43%	79
#13	(€ 100, with 90%, now)	(€ 100, for sure, 1 month)	19% vs. 81%	79

Choice #12 shows the trade-off of receiving an outcome with higher probability but later. In this case, the modal preference is to choose the sooner but less certain prospect. Choice #13 is constructed from Choice #12, but with a larger outcome. For larger outcomes, most subjects switch and want the later but more certain prospect. We call this preference reversal the *subendurance*.

The subendurance implies that the trade-off between delay and probability is outcome dependent. People are more enduring as the outcome increases. To account for the subendurance, one needs to make the probabilistic discount rate dependent on the magnitude of the outcome, or

$$V(x, p, t) = \frac{v(x)}{e^{d(\ln(1/p) + r(x)t)}}, \quad (5)$$

where $r(x)$ is a decreasing function of the outcomes. Hence, for small outcomes, time runs faster than for large outcomes.⁷ In summary, the core behavioral findings of the risk and time domain can be encoded in a *value function*, $v(x)$, a psychological distance function, $d(\ln(1/p) + r(x)t)$, and a probabilistic discount rate function, $r(x)$, that regulates the trade-off between risk and time.

Historically, diminishing sensitivity to risk distance has been incorporated by means

⁶Interestingly, reversals #6–#10 and #8–#11 rule any of the following forms: $V(x, p, t) = f(t)w(p)v(x)$, or $V(x, p, t) = w(p)v(x, t)$, or $V(x, p, t) = f(t)v(x, p)$. To see this, note that in #1 the time is the same in both prospects. Hence, in comparing both evaluations the term $f(t)$ would drop, and the preference be driven by the values of p and x . But in #10 time also drops, and the tasks have the same values of p and x , hence no preference reversal should be expected. Similarly, the term $w(p)$ would disappear from the utility comparison in both #8 and #11.

⁷Preliminary experimental evidence suggests that if time is measured in months, then $r(x)$ could be written as R/x , with $R = \$1.5$ [21]. Thus, for an outcome of \$15, time fades at a monthly rate of 10%, for \$150 at a monthly rate of 1%, and for \$1500 at a monthly rate of 0.1%. Demographical variables influence the probabilistic discount rate: it decreases with age at a rate of 5% per year, and it is 35% higher for females; the passage of one time unit carries more “uncertainty” for the young and for females [22]. The probabilistic discount rate influences the discount rates (the marginal rate of substitution between x and t in V). Therefore, if r decreases with age, we expect a higher willingness to wait for a larger outcome as we grow older.

of a nonlinear probability weighting function (*pwf*), $w(p)$, by Kahneman and Tversky [15], and diminishing sensitivity to time distance by means of a time discounting function (*tdf*), $f(t)$, exhibiting decreasing impatience. The translation between these classical behavioral models and our framework is given by the following equality:

$$\begin{aligned} V(x, p, t) &= e^{-d(\ln(1/p) + rt)} v(x) = w(pe^{-rt}) v(x) \\ &= f(t + \ln(1/p)^{1/r}) v(x). \end{aligned} \quad (6)$$

A concave *pdf*, a subproportional *pwf*, or a subadditive *tdf* are all equivalent. If in addition the *pdf* crosses the identity line from above, then the *pwf* is inverse-S-shaped and crosses the identity line from above. Of course, a *pdf* equal to the identity, a *pwf* equal to the identity, and an exponential *tdf* (constant impatience) are all equivalent.

Sensitivity to Gains and Losses

What is the shape of the value function one encounters in experiments? First, subjects do not have a stable utility function u over absolute consequences that determine $v(x)$. Rather, what is stable is a reference-dependent value function. That is, a given gain is perceived the same regardless of the base level of wealth. Decision makers would evaluate the prospect of a gain of \$10,000 when their income is \$90,000 the same as a gain of \$10,000 when their income is \$190,000. In both cases, we assume that the reference point has adjusted to the habitual income level. Hence, the absolute income does not significantly affect the preference over the prospect of a gain of \$10,000, because the habitual income level will be factored away from consideration.⁸

Reference dependence would not matter if v were approximately exponential, as the exponential shape makes subject's preferences invariant to reference effects. An exponential value function would imply diminishing sensitivity to gains, and

increasing sensitivity to losses. But this is far from what is usually found. Instead, subjects exhibit diminishing sensitivity to both gains and losses. In other words, v is S-shaped. Moreover, subjects have more sensitivity to losses than to gains of equal magnitude, that is, v is steeper for losses than for equivalent gains [15] (Figure 1).⁹

Empirical Estimation of the Descriptive Model

Various authors have attempted to empirically determine the prevailing shape for v and w (or d). The frequent form that has been adopted is $v(x) = x^\alpha 1_{x \geq 0} - \lambda(-x)^\alpha 1_{x < 0}$ and $d(z) = \delta z^\gamma$.¹⁰ This power specification for the *pwf* yields the Prelec form [27], $w(p) = e^{-\delta(\ln 1/p)^\gamma}$, and the Ebert and Prelec form [28] for the time discounting function, $f(t) = e^{-\delta(rt)^\gamma}$. The model allows for sign-dependent sensitivities to risk and time distance. Hence, we use δ^+ and δ^- , depending on the sign of the outcome (the exponents α and γ for gains and losses are found to be similar, and we make them the same.) If rational decision makers were characterized by the pair (ρ, r) , their irrational counterparts could be characterized by five parameters $(\alpha, \lambda, \gamma, \delta^+, \delta^-)$. Plausible values for these parameters based on literature averages are [29]

$$\begin{aligned} (\alpha = 0.85, \lambda = 2.25, \gamma = 0.65, \delta^+ = 1, \\ \delta^- = 0.87). \end{aligned}$$

In this framework, individual or demographic differences in risk attitudes boil

⁸Strong reference dependence, together with a reference that adapts to past income or that of the others, explains the happiness treadmill [23].

⁹The combination of reference dependence and loss aversion explains why, out of the following two equivalent proposals, the second has a stronger impact [2, p. 37]: (i) if you use energy conservation methods, you will save \$350 per year; or (ii) if you do not use energy conservation methods, you will lose \$350 per year.

¹⁰A more satisfactory behavioral specification could be the expo-power value function $v(x) = (1 - \exp(-\beta x^\alpha))/\beta$ as it contains both the power and exponential as particular cases, and it might be empirically more accurate [21, 24]. Regarding the *pwf*, popular specifications such as that of Tversky and Kahneman [25] or Goldstein and Einhorn [26] forms produce unnatural *pdfs*. Hence, we stay with Prelec's [27] form.

Figure 1. The behavioral model is characterized by three functions. The *value function* (a) describes diminishing sensitivity to gains and losses, including loss aversion. The *physiological distance function* (b) describes diminishing sensitivity to risk and time distance. The *probabilistic discount rate* (not drawn) describes the exchange rate between time and probability (which may depend on the magnitude of the outcome and demographical variables).

down to making these parameters dependent on say age, gender, and education. Interestingly, income has little influence on the parameters, confirming the validity of the reference-dependent model. Females often exhibit more risk aversion than males. In a rational framework, this implies a more concave utility function. But in a behavioral framework, risk attitudes are a complex composite of curvature of the value function and of the *pwf*. Booij *et al.* [29] confirm previous findings that gender differences in risk attitudes are not found on the curvature parameters, but on the parameter of loss aversion (λ is higher on average by 0.25 in females).

Older people seem to value money more linearly, with a 50 year age difference being associated with a power that is 0.15 higher. This effect works to reduce risk aversion, but it is countered by more nonlinear weighting of probabilities (γ in older people lower by 0.3).¹¹ Education, defined as having a higher vocational or academic education, does not affect utility curvature, nor is it associated with a more linear weighting of probabilities. However, education is associated with a

lower degree of loss aversion (λ in the highly educated is lower by 0.32), which suggest that the reduction in risk aversion with years of schooling that is often observed [32] stems mainly from lower λ .

Emotions, for instance, are naturally incorporated in this model. Hsee and Rottenstreich [33] show that in high arousal emotional states the curvature of both v and d increase (α and γ decrease with arousal). Thus, stressed individual are more risk averse for gains, and more risk seeking for losses of moderate probability [34]. An obviously exciting research area is to connect these functional specifications with findings from neuroimaging experiments [35].

ESTIMATING SUBJECTIVE PROBABILITY

Going back to the work of Kahneman, Tversky and their colleagues in the 1970s, there have been many empirical demonstrations of peoples' difficulties in estimating the quantities needed for a rational decision. In the previous section we have focused on the behavioral replacement of the utility function, and assuming that the delay and the probability were objectively provided. Here, our concern is the estimation of the probability when this parameter is to be estimated subjectively.

There are numerous biases that question the accuracy in the estimation of

¹¹The total effect of these estimates depends on the prospects under study. For prospects that entail a small probability of a large gain one may find risk aversion to decrease with age, while in those that do not, increasing risk aversion is more likely, which is what is usually found [30–32].

probabilities. Most of these biases affect the process of forming quantity judgments in general, and some are specific to probabilities. Subjects use a number of heuristics such as *similarity/representativeness*, *availability*, or *partition dependence* to come up with probability estimates. These heuristics may perform relatively well in natural environments, but their simplicity necessarily produces systematic mistakes. One example is the representative heuristic, which judges the probability of an element to belong to set by its similarity to a representative sample. For instance, subjects are given the description of a woman called Linda. Given the description, they think it is more likely that Linda is “a bank teller involved in feminist movement” rather than “a bank teller.” But the second set is larger than the first, so this likelihood ordering is absurd. The availability heuristic (judging probabilities by the facility with which our mind produces examples) leads us to give higher probability to events that are easier to imagine, or appear more often in the news [36]. Finally, when subjects are asked to assign probabilities to an event that has been partitioned in n cases, they tend to give probabilities of $1/n$ to each partition [37].

It appears to be difficult for people to apply Bayes theorem and correctly modify the probabilities based on a new piece of evidence. More specifically, laypeople and also professionals such as medical doctors and judges seem to be putting too little weight on the prior probability (this phenomenon has been called *base rate neglect*; [38]). This explains why, for example, doctors and patients often believe that the probability of suffering from a disease such as an HIV infection is almost one if one tests positive. While the sensitivity and specificity of medical tests is often close to one, the *a priori* probability (the base rate) of suffering from a disease, such as HIV infection, is very low. Thus the accurate, when taking into account base rates, value of the probability is medium. Note, however, that base rate neglect can be alleviated by the use of formats that represent probabilistic information so as to facilitate computation, such as “natural frequencies” [39].

Probability judgments can be made more accurate by combining the estimates of different sources. Subjects often fail to appreciate the power of this averaging principle, and rather fall in the trap of *chasing the expert* [40].

Another empirical phenomenon that refers to peoples’ probabilistic thinking is *overconfidence*. Various phenomena have been labeled overconfidence and there are many different definitions [41]. Sometimes overconfidence is measured by the miss-calibration of subjective probabilities, which equals the discrepancy between subjective probabilities and objective probabilities. For example, if one believes that the probability of a fair coin landing heads equals $1/3$, then their miss-calibration would equal $1/2 - 1/3 = 1/6$. Other measures include overestimation. That is, if a student who took a 10-item quiz believes that he answered five of the questions correctly when, in fact, he got only three correct, then he has overestimated his score by two items.

It was originally thought that overconfidence is very widely spread. There is no doubt that people are overconfident under some conditions. But during the last 20 years or so, researchers have questioned the empirical adequacy of the claim that most people are overconfident most of the time. Problems have been identified in the way researchers select items, how data are analyzed, and other problems including overconfidence as a reflection of regression-to-the-mean-like artifacts [41]. There are, however, no comprehensive reviews available of the evidence for overconfidence across the different phenomena labeled as overconfidence.

We can finally ask what is the normative status of these biases. For instance, is overconfidence always bad. Or is it? If people are overconfident, it might be that they are overconfident for a reason. In other words, overconfidence may confer adaptive advantages by, for example, increasing resolve, increasing the ability to bluff opponents, and winning net payoffs from risky opportunities despite occasional failures. Again, systematic mistakes reflect the use of simple processes to handle complex problems. If we were constrained to use simple processes, then the

heuristics most people use might be efficient, as they provide quick and relatively accurate answers most of the time.¹²

FACING TRADE-OFFS

After it was empirically demonstrated [43] and acknowledged that human behavior does not always conform to the ideal of unbounded rationality, different theorists took different approaches to building a behaviorally sound decision theory. One approach, that is highlighted in the first part of this entry, is to see how the expected utility benchmark can be modified so that it accounts for the major empirical phenomena. One may note that this approach differs from that of Herbert Simon. The construct of an expected utility function does not feature prominently in Simon's work. An alternative approach to a utility-based theory of rationality is the study of "how actual people make decisions without calculating utilities and probabilities" [44, p. 8]. Rather than forcing subjects into a

choice paradigm constructed from artificial comparisons between pairs of prospects, the focus is to the study the actual process subjects follow to reach a decision. This latter approach is the one we adopt in this section, as applied to complex decisions among multiattributed alternatives.

You are a member of the search committee for a postdoctoral research fellowship. The secretary hands to you the packet with the applicants' cover letters, vitas, reprints, and recommendations. You discover that there are more than a dozen applicants and there is simply not enough time to read all material before the committee meets tomorrow. And, yet, you must have good reasons for the short list you propose. What do you do?

The Rational Model: Multiattribute Utility Theory

Let us discuss first what it is that supposedly you should do. The standard theory of multiattribute choice is Keeney and Raiffa utility theory [45]: Assume that the value x_{ij} of option X_i on attribute j can be mapped onto a utility $u_j(x_{ij})$. For example, a candidate may have zero refereed publications, and thus also zero utility from publications. Under some technical assumptions, for example, of preferential independence it can be proven that there exist scalar weights w_j so that the total utility of option X_i equals $\sum_j w_j u_j(x_{ij})$. The weights can be interpreted as quantifying how utility due to one attribute can be traded off against utility due to other attributes. According to multiattribute utility theory, the decision maker must choose an option with maximum total utility. The rational model can justify a number of specifications, such as the multiplicative form if there are interactions between the attributes.

The field of prescriptive decision analysis is concerned with finding ways of restructuring the decision problem so that people can provide better estimates, and, more generally, correctly apply utility theory in situations with multiple attributes, under both certainty and uncertainty [46,47].

¹²Evolutionary arguments are often invoked to support that rationality is supposed to be the rule. If evolution has endowed us with such perfect organs for perception and movement, why should our cognitive abilities be systematically biased. In a recent paper, Livnata and Pippenger [42] give an evolutionary argument that support "systematic mistakes" as more adaptive than perfection. The key argument hinges on assuming a bound on the processing capacity of the brain. They model the brain as an informational processing network with fixed number of components. If the capacity is fixed, then an informational processing network that handles a larger set of inputs with systematic mistakes is superior to an informational processing network that handles a smaller set of inputs with no mistakes. This result suggests that departures from rationality in humans are explainable by natural selection, as evolution operates under constraints. If the information processing capacity is upper bounded, there is a trade off between the exactitude of the response and the size of the environment the processor can handle. A processor that gives approximately correct answers to a broad domain of problems is superior to a processor that gives exact answers to a narrow domain of problems.

The Behavioral Model: Noncompensatory Heuristics

This is a clear theory but it is not always so clear if people can apply it in practice. To apply it, subjects must measure x_{ij} , estimate their utility function $u_j(x_{ij})$, and weight w_j for each attribute j . For instance, the estimates of attribute weights turn out to be influenced by variables such as the range of the attribute values that are theoretically irrelevant, or the base attribute chosen to elicit the trade-offs with the rest of attributes. And, professionals, such as urban fire-ground commanders, often cannot or refuse to provide utilities (for more examples, see Katsikopoulos and Fasolo [48]). A field called *naturalistic decision making* is especially critical of the applicability of utility theory to real-world decision problems [49].

Let us say that you will not apply multi-attribute utility theory. Here is something you could do instead: You first eliminate all candidates who have no refereed journal publications. From the pool of remaining candidates, you further eliminate all of those who have at least one recommendation that is lukewarm or negative.

Tversky [50] proposed elimination by aspects (EBA) as a model of how people choose among multiattribute options. In EBA, the attributes are ordered and considered one at a time. In the example above, the first attribute is the number of publications and the second attribute is the number of nonpositive recommendations. When one attribute is considered, every option that has a value on the attribute that is inferior to a predetermined aspiration level is eliminated (unless all the alternatives are unacceptable on that attribute). In our example, the aspiration level on the number of publications is one and the aspiration level on the number of nonpositive recommendations is zero. The heuristic terminates when there is just one alternative left, or all attributes have been considered. In the latter case, we can choose randomly from the set of noneliminated options.

EBA implements a simple way of facing trade-offs among attributes: by, in fact, not making them. In the example above, excellent recommendations or a great cover letter

do not compensate for lack of publications. Models of multiattribute choice under certainty that do not make trade-offs among attributes are called *noncompensatory*, and often involve a *lexicographic* of elimination of alternatives by sorted criteria.

There are a number of ways by which people could be ordering attributes. A simple assumption is that attributes are ordered randomly (this is the case for EBA). It is, however, more psychologically plausible that the order of attributes depends on the population from which pairs of options are sampled. In the take-the-best (TTB) heuristic [51], attributes are ordered by their validity. Given a pair of randomly sampled options X_1 and X_2 such that X_1 has the higher “true utility” for a decision maker, the validity of attribute j is the conditional probability $Pr[x_{1j} = 1, x_{2j} = 0 | x_{1j} \neq x_{2j}]$. It turns out that the validity of an attribute is equal to a positive linear transformation of a correlation measure between the attribute and the true validity. This correlation measure is naïve in the sense that it ignores the interdependencies between attributes.

EBA, and other noncompensatory models, capture the intuition that people often make decisions by using a limited amount of resources, such as time, information, and computation. For example, in EBA, the decision maker does not look up all available information because s/he does not use all attribute values of all options. In our example, the recommendations attribute is not used for some of the candidates (those with zero publications). The cover letter attribute is not used for any of the candidates. In sum, a shortlist of candidates is chosen quickly, based on a few pieces of information. Note also that EBA is not computationally demanding as no sophisticated operations are applied to the pieces of information that are actually used. Unlike utility theory, attribute values are neither weighted nor aggregated. They are compared to a fixed threshold.

Simon [52,53] is widely credited as being the first who forcefully claimed that people use limited time, information, and computation when making decisions. The resources available for making decisions can be limited because of the way the decision problem is

structured in the real world. For example, the time you have for reviewing applications may be short because you have many other things to do as well. Often the computations needed for implementing a compensatory model that makes trade-offs are beyond the capacity of humans or machines, as in deciding your next move in a game of chess. Finally, the decision maker may prefer a simpler decision process in order to have a better understanding of how a decision was reached and be able to justify it to others.

In psychology, Tversky, Kahneman, and their colleagues [43,54,55] provided extensive evidence for Simon's claim. They popularized the term *heuristics* for simple rules of thumb that people use for making decisions. In a review of 45 studies on tracing human decision processes, Ford *et al.* [56] concluded that "noncompensatory strategies were the dominant mode used." Gigerenzer and his colleagues [44,51,57] documented the use of noncompensatory heuristics in a variety of fields such as biology, engineering, and law.

In sum, there are good reasons for believing that people do make decisions by using simple noncompensatory heuristics. The analytical study of these heuristics has been facilitated by the use of mathematical models.

Despite their naiveté lexicographic heuristics such as EBA and TTB can, under some conditions, lead to decisions that increase total utility in comparison to benchmarks such as linear regression. Payne *et al.* [58] and Gigerenzer and Todd [51] demonstrated this by computer simulations. A difference between the two studies was that in the former the true utility of options was assumed to equal the value of a linear combination of attribute values, while in the latter the true utility was exogenously given. Further analyses have uncovered mathematical reasons for the success of lexicographic heuristics [59], provided the attributes are sorted correctly before applying sequential elimination of alternatives. For example, the heuristics are optimal if and only if attribute validities are very far apart [60], or there exists a cumulatively dominating option. Cumulative dominance provides a structural justification for the reasonable performance of a broad class of lexicographic heuristics [61].

CONCLUSIONS

The extension of the behavioral model to domains with multiple risky outcomes and/or multiple time periods is still an open problem. For multiple-outcome lotteries that resolve now, cumulative prospect theory is the prevailing extension [25]. However, empirical evidence is mixed [62,63] and replacements such as the TAX model proposed by Birnbaum [64] may outperform cumulative prospect theory.

In the time domain, the extension to multiple outcomes received at different time moments is still an open problem. With multiple outcomes received over time, one needs to account for possible changes in reference points. It has been shown that subjects miscalculate these changes, thinking that future reference points will be closer to current reference points. In reality, reference points may change more than anticipated (*adaptation bias*). Adaptation bias is a particular instance of the more general *projection bias* [65]. In complex decisions, the behavioral model also needs to specify the type of simplifications subjects may perform to simplify the problem; one such simplification being *narrow choice bracketing* [66]. Projection bias and narrow bracketing introduce the distinction between predicted/decision utility and realized/experienced utility.

Diminishing sensitivity to risk distance accommodates anomalies of the classical model such as the Allais paradox [14], the coexistence of gambling and insurance, betting on long-shots at horse races [67], and the avoidance of probabilistic insurance [68]. In the time domain, evidence for diminishing sensitivity to time distance is abundant [69–71], and models incorporating this effect are now part of economic analysis [72], and are known under the name of *diminishing impatience* of hyperbolic discounting models. Persistent phenomena such as repeated procrastination are explained by decreasing impatience [73]. Loss aversion explains the endowment effect, and excessive risk aversion in risks involving potential gains and losses [74]. For risk with only losses, diminishing sensitivity yields to chains of bad decisions known as *escalation of commitment*.

The subendurance explains the attractiveness of consumption loans: the payment is made smaller through monthly installments and delayed in time. The model predicts that the attractiveness further increases if the payments are made smaller by increasing the frequency of payments (say weekly instead of monthly). The subendurance indirectly explains the observation that discount rates depend on the magnitude of the outcomes, known as the *magnitude effect* [16].

The approach of noncompensatory heuristics has also been recently used to describe how people handle trade-offs under uncertainty. For choices between gambles, it has been shown analytically that the so-called priority heuristic implies major violations of expected utility theory such as the common-consequence effect, the common ratio effects, the reflection effect, and the fourfold pattern of risk attitudes [75].

Risk plays a central role in decision making. Accordingly, risk has been a popular research topic for more than four decades. Finding a generic definition of risk is hard, since this term is used in many areas such as economics, political science, management science, and medical research. However, one thing in common is that risk is always related to both the negative outcomes and uncertainty. In addition, we know that risk is normally subjective and constructed by a human's perception process. But indeed how do people perceive risks? Is there any model capable of describing this procedure and predicting people's perceived risk? In this article, we focus on empirical studies of perceived risk.

In operations research/management science as well as in psychological research, much effort has been spent on defining the subjective perception of risk. The central topic is how we can define or predict people's perceived risk of a risky option based on the characteristics of that option. The basic structure has been simply depicted in Fig. 1 below.

In Fig. 1, vector C represents an option's characteristics related to its perceived risk. The characteristics can be objectively known or can be based on subjective judgments, and the perceived risk is a real function of these characteristics. Thus, the main research objective is to find what C includes and what the functional form $f(\cdot)$ is.

On the basis of different contexts that risk perception models can be applied to, we roughly divide this topic into two subcategories. One focuses on perceived risk of monetary options, such as risky investments and gambles. The other focuses on societal risks such as natural disasters, terrorist attacks, and new technologies. These subcategories are not mutually exclusive. However, they do have many differences. For instance, monetary options can be explicitly interpreted as gambles with numerical payoffs and probabilities, but societal risks normally are hard or impossible to be transformed in that way. As a result, in the first category, C usually contains objective values from the option rather than subjective values from people's judgments, which are used in the second one.

In the next section, we review the risk perception studies of monetary risks. The section titled "Perception of Societal Risks" mainly describes the research on societal risks in a psychometric framework. The section titled "Further Developments of Risk Models" briefly introduces some developments of perceived risk. The last section concludes the article and gives some possible future research directions.

PERCEPTION OF MONETARY RISKS

Broadly speaking, monetary risks include all options whose consequences and chances of these consequences can be described in a numeric form. For example, a hit and run accident can be regarded as an event with monetary risks (i.e., a gamble) if the driver has a specific subjective probability (e.g., 50%) that there are witnesses who can recognize his/her plate number and will report to the police. He/She knows that the consequences should be a specific monetary loss (e.g., \$500). Monetary risks represent a large group of events in which people focus on the monetary consequences. In the remainder

of this section, we basically deal with abstract gambles. However, keep in mind that those gambles are just parsimonious representations of many events in real life.

Figure 1. Basic structure of perceived risk models.

The objective of empirical research on perceived risk models is to discover and verify C and $f(\cdot)$. In most studies, they are first developed on the basis of a series of assumptions or axioms (see Jia *et al.* [1] and article titled *Axiomatic Models of Perceived Risk* for details), then they are tested by experiments. There are two possible ways to test the proposed model: (i) to test the validity of its assumptions or (ii) to test the power of this model using people's holistic judgments; either way verifies the model. In the following parts of this section, we do not differentiate between the two ways to test models but focus on the descriptive tests of different models.

Experiments on Models Using Moments

Just as the name implies, the moments models take C as moments of the distribution of outcomes. These experiments were conducted in the late 1960s–1980s. Coombs and his colleagues [2–5] used the moments of the distribution of payoffs such as mean, variance, and skewness to predict people's risk perceptions. Their work was motivated by Coombs' portfolio theory [6,7], which stated that people face a trade-off between the expected value and perceived risk when choosing among risky options. For example, in one of Coombs and Huang's papers [2], they formulated the gambles into the form of $[a + b, 50\%; b - a]^c$ (i.e., a gamble gives you a 50% chance to win " $a + b$ " and a 50% chance to win " $b - a$," and this gamble will be repeated " c " times), which has a mean factor " b ," a dispersion factor " a " and a repeat time factor " c ." Varying the value of " a ," " b ," and " c ," they asked subjects to rank the perceived risk of several sets of gambles. Their data supported the moments model. However, later Barron [8] found contrary results in his experiments.

From a more rigorous modeling approach, Pollatsek and Tversky [9] and Rotar and Sholomitsky [10] provided an axiomatic system that supported their risk theory. Their axioms were also tested by experiments [3,4]. Generally speaking, the moments models are not totally successful as descriptive models since the empirical tests give mixed results. However, using distributional variables to predict people's perception could be suitable in the sense that it is very intuitive. Believing that, Lopes [11] used complex gambles (i.e., gambles with more than three outcomes) as stimuli to test distributional models and stated that "the data support the distributional model of risk . . . , and they show that people's judgments of possible risks are similar functionally to judgments of distributional inequality."

Luce's Assumptions and Related Experimental Results

Luce [12,13] made assumptions to define several alternative measures of perceived risk. Please refer to Refs 12–16 and the article titled *Axiomatic Models of Perceived Risk* in this encyclopedia for the details of the derived measurements and their extensions. Here we only describe the two key assumptions. Specifically, the first assumption claimed that if all outcomes of a gamble are multiplied by a constant number, the risk either increases additively or multiplicatively. The second assumption claimed that there might be two ways to transfer the random variable (i.e., a gamble) into a single number (i.e., the perceived risk): (i) to aggregate some transformation of the random variable or (ii) to aggregate some transformation of the density function of the random variable. Notably, this is different from the moments models since it derives measures of risk by assuming some specific characteristics of people's risk judgments. Luce's work [12,13] only provided several possible models. Then, there were several studies testing both the assumptions and people's holistic judgments of his model. For example, Keller *et al.* [14] empirically tested the axioms proposed by Luce. In their study, they asked subjects to rank or directly compare several groups of well-defined gambles.

They observed “remarkable consistency in the risk judgments of the US and German subjects.” They also found many other interesting results: first, adding a positive number to all payoffs decreased the risk of the gamble; second, when the probability of loss was high, it had relatively more influence on people’s risk perception, whereas when the probability of loss was low, the amount of loss had more influence; third, the skewed gambles were more risky than corresponding symmetric gambles. Almost at the same time, Weber [17] tested the validity of Luce’s assumptions and got the result that two-thirds of the data supports the additivity assumption. On the basis of empirical results [17,18], Luce and Weber [15] axiomatized a risk perception model called *conjoint expected risk* (CER), which states that the perceived risk of a gamble is a weighted function of five dimensions: probability of gain, probability of loss, probability of status quo, expected values of gain and loss. Weber [18] ran several experiments testing the holistic validity of the CER model and found that (i) the CER model could predict people’s risk perception for risky gambles relatively well and (ii) the CER model was not very powerful to deal with two-outcome gambles. Later, Weber and Bottom [19] empirically tested the adequacy of the axioms of the CER model, and found support for transitivity (if A is more risky than B , and B is more risky than C , then A is more risky than C) and monotonicity (if A is more risky than B , then for any C , $p \cdot A + (1 - p) \cdot C$ is more risky than $p \cdot B + (1 - p) \cdot C$). In addition, they found that the conjoint structure had more power on gambles with negative outcomes than on gambles with positive outcomes.

Two-Attribute Models for Perceived Risk

By decomposing a lottery (X) into its mean ($\bar{X}$) and its standard risk ($X' = X - \bar{X}$), Jia *et al.* [1,20] (see also article titled ***Axiomatic Models of Perceived Risk*** in this encyclopedia) used a two-attribute model to represent people’s preference such as value and risk. The model was based on expected utility theory [21]. Since the general form of this model is very flexible, by varying the functional forms of each part, this two-attribute model may be

transformed into many existing models such as Pollatsek and Tversky’s risk model [9] and Bell’s disappointment model [22]. It also included possible different effects between positive payoffs and negative payoffs, which were emphasized in prospect theory [23]. For a detailed description, please refer to the article titled ***Axiomatic Models of Perceived Risk*** in this encyclopedia. The fundamental assumptions (axioms) of this model were also tested, and “the data indicate that the participants’ responses were generally consistent with the key assumptions of risk-value models” [24].

In this section, we reviewed several studies on perceived risk of financial gambles. As mentioned earlier, this type of gamble is an abstract representation of a large group of real-life events. Thus, they are important contributions to behavioral decision research as well as public policy making. Though so far no functional form $f(\cdot)$ has been proved to be universally valid even in very simple situations, researchers did find several patterns that are generally consistent among groups. They are (also see ***Axiomatic Models of Perceived Risk***):

1. When the variability (range, variance) of gambles increases, the perceived risk increases [2,25].
2. When the expected loss increases, the perceived risk increases [2,25].
3. When a constant amount is subtracted from the positive outcome, the perceived risk increases [14].
4. When all outcomes of a zero-mean lottery are multiplied by a positive number, the perceived risk increases [26].
5. When a zero-mean gamble is repeated many times, the perceived risk increases [26].
6. A gamble repeated fewer times with a high expected loss is more risky than a gamble repeated more times with lower expected loss [25].

We believe it is unlikely that a mathematically simple form can capture all aspects of perceived risk in realistic situations, but we do believe that every step further in the

research on perceived risk will shed some light on how people really make decisions and what kind of information or framing can lead people to better decisions under risk.

PERCEPTION OF SOCIETAL RISKS

Is taking a flight more risky than driving a car? Is nuclear power more risky than smoking? Probably most people will say yes in both cases. However, in terms of the monetary risks that we introduced in the last section, their answers are wrong, since there is no evidence that the latter ones have lower probabilities of losses or lower potential losses to the human beings. But why do people think in that way and are they right? As we said at the beginning of this article, people have different interpretations of risks [27]. Experts normally define the risk of a certain event by its consequences (e.g., annual fatalities) and the probability of those consequences. A lay person's judgment of perceived risk is related to additional characteristics of that event. Thus, when we try to predict the general public's perception and response to some risky events, especially those events with rare and delayed consequences, the tools we used in monetary risks do not suffice. We need to employ broader factors that relate to people's risk judgments. In this section, we focus on a special type of risks, which are sometimes hard to convert to pure numeric presentations. They are defined as societal risks.

Consider Fig. 1 again. People's perception of any kind of risk should come from the characteristics of this risk (C). It can be objective or subjective. In the domain of financial risks, we use objective values to describe people's risk perception. However, in the domain of societal risks, we use both objective and subjective characteristics. Slovic *et al.* [27–29] developed a psychometric paradigm for societal risks that can be used to understand different risks in a multidimensional manner. They used psychological scaling and multivariate analysis methods to give a quantitative representation to risks. The dimensions vary among different studies. For

example, in Ref. 28, the authors employed nine dimensions such as voluntariness, immediacy of effect, known to exposed, known to science, controllability, newness, chronic-catastrophic, dread-common, and severity of consequences. The explanations of these terms [28, p. 133] are as follows: “(i) Voluntariness: Do people get into these situations voluntarily? (ii) Immediacy of effect: To what extent is the risk of death immediate—or is death likely to occur at some later time? (iii) Known to exposed: To what extent are the risks known precisely by the persons who are exposed to those risks? (iv) Known to science: To what extent are the risks known to science? (v) Controllability: If a person is exposed to the risk of each activity or technology, to what extent can he/she, by personal skill or diligence, avoid death while engaging in the activity? (vi) Newness: Are these risks new, novel ones or old, familiar ones? (vii) Chronic-catastrophic: Is this a risk that kills people one at a time, or a risk that kills large numbers of people at once? (viii) Dread-common: Is this a risk that people have learned to live with and can think about reasonably calmly, or is it one that people have great dread for—on the level of a gut reaction? (ix) Severity of consequences: When the risk from the activity is realized in the form of a mishap or illness, how likely is it that the consequence will be fatal?” On these nine scales, people made judgments about their current perceived level of each dimension, which helped researchers to further analyze different risks with respect to their characteristics. In their study, they also found that these factors were not independent. Peters and Slovic [30] found that all the above dimensions could be distilled into two primary factors: dread and risk of unknown, which explained above 90% of the variance.

Numerous studies have been conducted using the psychometric paradigm. For example, Feng *et al.* [31] examined patterns of risk perceptions and decisions when people are facing consumer product-caused quality risks. They focused on the contexts of contaminated pet food and lead-painted toys. They evaluated these two risks and positioned them into a two-factor space diagram

Figure 2. Location of two risks within the two-factor space. (From Feng *et al.* [31], with authors' permission).

(as shown in Fig. 2) of various societal risks. Comparing with other risks, they found that these two risks were similar in the sense that they were very closely positioned in the diagram. As stated in Ref. 27, the locations of risks in the two-factor space can largely predict people's attitudes toward the risks and also can help government and authorities to deliver the right information in the sense that it can help the general public estimate the risks correctly.

FURTHER DEVELOPMENTS OF RISK MODELS

Risk-As-Feelings Hypothesis

If we compare the studies in the last two sections, we notice a fundamental difference. The first group of studies tried to use objective factors of risks to evaluate the perceived risk. In other words, these models judged the risk based on an individual's anticipated monetary outcomes. For example, consider a lottery that gives a person a 50% chance to win \$100 and a 50% chance to lose \$85. The perceived risk of this lottery, in the first group of models, basically comes from the projections of loss and gain and their chances to occur. However, in the psychometric models, researchers used different psychological dimensions to predict a person's perceived risk. They include not only anticipated outcomes after their decisions but also feelings before they make decisions. In a highly cited paper, Loewenstein *et al.* [32] proposed a risk-as-feelings hypothesis and defined the former consideration as *anticipated emotions* and the latter consideration as *anticipatory emotions*. The risk-as-feelings hypothesis emphasizes the role of the psychological affect experienced at the moment of the decision making, shows that the emotional reactions and the cognitive judgments are often different and also states that, when emotional reactions and cognitive reactions conflict, the emotional side normally drives an individual's behavior. In their article, they also showed several determinants that could change people's emotional responses, such as mental vividness, time interval, and evolutionary makeup. The risk-as-feelings hypothesis has been used in various fields including

decision theory, psychology, and marketing. For example, Weber [33] employed the risk-as-feelings hypothesis to explain why global warming does not scare people. She explained that the affect played an important role in risk perception and people would take action only if they had a vivid personal experience. However, since global warming is not a very salient event, and involves a great temporal distance, people tend to underestimate the risk associated with it.

A Hybrid Model

Holtgrave and Weber [34] compared two models of risk perception: the CER model and the psychometric model. They used both financial and health risk stimuli, and the CER model provided a better fit if both models were used separately. However, when combining the two models together, they found that the hybrid model could obtain the best fit.

Other than comparing the power between the two models, this research also demonstrates the relationship between them. It proves that Slovic's psychometric model still has an explanatory power even after controlling for the effect of probability and outcomes. In addition, this can be regarded as being in favor of the risk-as-feelings hypothesis.

Cross-Cultural Study of Perceived Risk

The previously described studies focus on constructing a generic model of human risk perception. However, how people perceive risks is not necessarily the same across cultures. If different cultures have different perceptions of the same risk, knowing the difference can help them when there are conflicts between them [35]. For example, a Chinese company and an American company may be both better off if they can reach a settlement that both parties find less risky and in which both get higher payoffs.

Weber and Hsee [35,36] investigated subjects from China, United States, Germany, and Poland by asking them to give both the buying prices and perceived risk of risky financial lotteries. They found that the Chinese participants were more risk-seeking than American participants in a traditional

expected utility framework. However, after some further analysis, they found that the difference came from the cross-cultural difference in risk perception. That is, the Chinese subjects and American subjects are similarly risk-averse but their risk perceptions of the same lottery are different. Furthermore, Weber *et al.* [37] compared the American and Chinese proverbs of risk and risk-taking to give concrete proof of the cultural explanation of the different risk perceptions. Their result is consistent with the conclusion of the cushion hypothesis in Ref. 35: the collectivist Chinese culture gives each individual more of a cushion against financial risks since collectivism usually cushions in-group people to face financial risks and deal with the possible negative outcomes together.

Different cultures also teach people to select different risks for attention. Douglas and Wildavsky [38] divided cultures into five types such as hierarchical, individualist, egalitarian, fatalist, and hermitic. In each culture, people selectively attend to some specific categories of risks and choose to ignore others. In this way, the perceived risk of an event will vary across different types of cultures.

CONCLUSIONS AND FUTURE RESEARCH

For more than 40 years, researchers of operations research/management science, economics, and psychology have paid much attention to perceived risk. In this article, we have only reviewed part of the literature. Generally speaking, in our article, the research can be categorized into two parts.

The first part focuses on monetary risks or any risks whose information can be distilled into payoffs and their probabilities. The objective is to find a parsimonious functional form to describe and predict people's perceived risk of simple gambles. However, human perception is a complex process and normally is hard to describe in a simple and good way. As a result, there is still a long way to go. Thus, several directions still need to be developed further: (i) a parsimonious way to

model people's risk perception; (ii) risk perception and decision making under risk are two well-developed research areas, but little work tries to link them together, so it would be interesting to consider how to incorporate perceived risk models into decision making under risk; and (iii) risk perception with a time dimension.

The second part focuses on psychological research of societal risks such as Slovic's psychometric models. The objective is to find a way to decompose people's processes for perception of risks. By analyzing an individual's feelings about risks in many dimensions, researchers can categorize risks and find appropriate ways to handle risks accordingly. We believe several directions need more investigation: (i) connecting societal risk research with risk communication research to find more effective ways of risk communication; (ii) development of a direct connection between locations of risks in the two-factor space and public policies; (iii) a way to help the general public perceive risks correctly; and (iv) investigating antecedents and consequences of societal risks.

Perceived risk research is a fruitful area. This article has only reviewed part of this work. Specifically, we have only focused on the empirical studies. For those who want to know more about the axiomatic research on perceived risk, please refer to the literature review part of Ref. 1 and the article titled *Axiomatic Models of Perceived Risk* in this encyclopedia.

DESIGN AND CONTROL PRINCIPLES OF FLEXIBLE WORKFORCE IN MANUFACTURING SYSTEMS

SEYED M. R. IRAVANI

Department of Industrial Engineering and
Management Science, Northwestern
University, Evanston, Illinois

INTRODUCTION

Advances in information technology and movement toward a global market that intensifies global competition have radically altered manufacturing systems over the past two decades. Under pressure to continually increase product variety, decrease price, and improve responsiveness to customers, firms have increasingly moved toward flexibility in their operations. Flexibility in manufacturing systems has been defined as the system's ability to adapt to changes in its environment [1]. Flexibility can be achieved through a variety of mechanisms, such as enhanced use of information systems, improved logistics, delayed product differentiation, small batch sizes, flexible (multipurpose) equipment, and flexible (cross-trained) workforce.

A cross-trained worker (also called an *agile worker*) is a worker who is trained to perform more than one type of task. Cross-training increases workers' utilizations by allowing them to use their idle time to perform other tasks in the system, which in turn increases the system's productivity. Cross-training also has other advantages, including (i) improving communication among workers, since they need to better coordinate tasks; (ii) effective problem solving, since more workers work on each particular task; (iii) improving worker satisfaction, due to greater compensation; and (iv) better ergonomic effects of task variety, due to less boredom and less repetitive tasks. Some examples of successful applications of utilizing flexible workforce in manufacturing systems are the module fabrication and assembly lines (cells) in John

Deere's planter factory, IBM's production line for unpopulated printed circuit boards, and the order picking operations at Gap Inc. [2].

In this article we focus only on the operational benefits of cross-training production/assembly workers in improving the performance of manufacturing systems, and we show how the performance of such systems can be improved through effective design and control of a flexible (cross-trained) workforce.¹

OPERATIONAL BENEFITS OF FLEXIBLE WORKERS

By "operational benefits of a flexible workforce" we mean the benefits that a cross-trained workforce provides in improving the operational performance of production systems, such as increasing throughput and reducing work-in-progress (WIP) inventory and cycle time. One obvious benefit of a flexible workforce is its ability to mitigate the effects of unpredictable disruptions such as worker absence. When more than one worker is trained for a given task, the absence of one worker will not have a significant impact on performance—in contrast to situations in which only one worker is trained for that task.

In this section we discuss the other two main features of a cross-trained workforce that are drivers of the operational benefits, namely (i) capacity balancing, and (ii) variability buffering.

Capacity Balancing

When a production line is not balanced in the sense that average processing times at all stations in the line are not equal, then some workers will have occasional

¹We would like to emphasize that the objective of this article is by no means to present a complete review of the literature on manufacturing systems with flexible workforce. An extensive literature on systems with cross-trained workforce exists, which we cannot discuss here due to limited space.

Figure 1. Two-station lines with two workers: (a) no cross-training, (b) Worker W2 is cross-trained.

idling. Cross-training enables workers to divide their effort among stations in the line, thus improving their utilization. Known as *capacity balancing*, this is the main driving force behind improving system performance through worker cross-training.

As an example, consider a two-station line in Figure 1a in which Worker W1 (Worker W2) is assigned to Station 1 (to Station 2). Processing a job at Station 1 takes 1 min (i.e., Station 1 has the capacity of producing 60 jobs an hour). After being processed at Station 1, the job is sent to Station 2. The processing time at Station 2 is 0.6 min, resulting in a capacity of 100 jobs an hour for that station. Assume deterministic processing times at each station, and suppose that ample jobs are available at the buffer of Station 1, but the buffer at Station 2 has a maximum limit of five jobs.

If workers are not cross-trained, then the maximum throughput of the line is $TH = 60$ jobs an hour, that is, the rate of the bottleneck Station 1. Note also that at the maximum capacity of 60 jobs an hour, Worker W2 at Station 2 is always idle for 0.4 min after processing a job at Station 2. One way to improve the performance of this line is *line balancing*. Line balancing requires redesigning the tasks at Stations 1 and 2 such that the processing time at Stations 1 and 2 become equal [3]. This is, however, often not possible, since not all tasks are easily divisible into smaller subtasks.

Another approach to improving performance, as shown in Figure 1b, is to cross-train Worker W2 at Station 2 to also perform the task at Station 1 (assuming that Worker W2 can work at Station 1 without interfering with Worker W1). This will increase the

throughput of the line significantly. Specifically, suppose that the line starts with five jobs at the buffer of Station 2. After serving those five jobs at Station 2 (which takes $5 \times 0.6 = 3$ min), Worker W2 switches to Station 1. At that time, the buffer of Station 2 has 3 jobs. Worker W2 processes one job at Station 1 (which takes 1 min) and then switches back to Station 2. At that time there will be five jobs at the buffer of Station 2, and this cycle repeats itself. Thus, in every 4-min cycle, five jobs are processed at Station 2 (by Worker W2), and five jobs at Station 1 (four by Worker W1 and one by Worker W2). Hence, the output rates of both stations are balanced at the rate of 75 jobs an hour. This results in a line throughput of $TH = 75$ jobs an hour, which is a 25% $(= (75 - 60)/60)$ increase in throughput due to cross-training.

As this example shows, capacity balancing, achieved in this case by cross-training Worker W2, can result in a significant improvement. The Japanese word *shojinka*² denotes this practice in the Toyota Production System. Shojinka achieves flexibility by changing the number of cross-trained workers in the line, and obtains greater productivity through capacity balancing.

Note that balancing capacity in our two-station line with two workers is simple. As the number of workers and the number of stations increases, capacity balancing naturally becomes more difficult. Nevertheless, simple Linear Programming (LP) models can be developed for balancing capacity in larger lines. For details see Refs 4–6 and references therein.

²*Shojinka* is a combination of *sho* (reduce) + *jin* (worker) + *ka* (to change)

Variability Buffering

As opposed to our simple example in which processing times were deterministic, in the real world there is always variability in the processing times in each station (due to such factors as changes in product mix, equipment failures, worker behavior, or lack of raw material). Cross-training can improve a system's performance not only through capacity balancing, but also by mitigating the negative impact of variability in the line.

Consider our example of a two-station line with no cross-training, and assume that the average processing time at both stations is 1 min. Suppose also that, the processing time at Station 2 is exactly 1 min (i.e., deterministic), but the processing time at Station 1 is uniformly distributed between 0.5 and 1.5 min.

Note that in this line with no cross-training, the capacity of the line is already balanced, since each station has an average capacity of producing 60 jobs an hour. If processing times at both stations were deterministic, then both workers had no idle time and the throughput of the line could reach its maximum of 60 jobs an hour. In this case there is no need for cross-training. When there is variability in processing times, however, the throughput of this line is less than 60 jobs an hour. This is because workers will have occasional idling, due to the variability in processing times at Station 1. Worker W1 can become idle due to the blocking of Station 1 (which occurs when the buffer of Station 2 is full), and Worker W2 becomes idle due to the starvation of Station 2 (which occurs when the buffer of Station 2 is empty). Cross-training workers will decrease workers' idle times and increase the utilization of each workstation, since instead of idling, each worker can work in the other station. This will in turn increase the throughput of the line. This benefit of cross-training that diminishes the impact of variability is called *variability buffering*.

WORKER CONTROL PRINCIPLES

The capacity balancing and variability buffering benefits of a cross-trained workforce cannot be fully utilized without a proper worker control policy. A *worker control policy* determines how each worker should allocate his or her time to the different tasks for which he or she is cross-trained. Specifically, in systems with cross-trained workers, a worker control policy is a series of rules that specifies (i) how long each worker should continue working at his/her current station, and (ii) which station she/he should switch to next.

As we will discuss in this article, the optimal worker control policies that take the greatest advantage of capacity balancing and variability buffering are often very complex. A desirable worker control policy is one that performs almost as well as the optimal policy, but it is also easy to implement and prevents worker confusion. In this article we present some easy to implement but effective worker control policies in systems with cross-trained workers. Our main focus is on production/assembly *serial lines*, which are also called *flow lines*. In an N -station flow line all jobs must be processed at station $i + 1$, after they are processed at station i ($i = 1, 2, \dots, N - 1$).

Regardless of the nature of the manufacturing environment, there are two common ways to release jobs into production lines: (i) push protocol, and (ii) pull protocol.

PUSH LINES WITH FLEXIBLE WORKERS

In a *push* line, new jobs are pushed into the production system according to a predetermined schedule. In push lines there is usually no control on the number of WIP in the line. Jobs are released into the first station in the line; in stable line, the throughput of the line will be the same as the job release rate [assuming no yield loss, [7]]. The objective in these lines is therefore to run the line so that a desired throughput is achieved with minimum WIP. For a given throughput (i.e., job release rate), this is equivalent to minimizing the cycle time.

One important consideration in push lines is the stability of the line. If the job release

rate is larger than the capacity of the line, then the WIP in the line will increase to infinity. A *stable* push line is defined as a line in which the average WIP in the line is finite.

Single-Worker Push Lines

Production lines with a single server are common in manufacturing systems. They are often known as one-worker manufacturing cells, in which one worker is fully cross-trained to perform all tasks in the line.

Consider a two-station push line in which one fully cross-trained worker is in charge of both stations; suppose also that the switchover times between stations is negligible (i.e., is zero). Switchover time D_{ij} between Station i and Station j is the time elapsed from when the worker leaves Station i to when the worker can start processing a job at Station j . Switchover time D_{ij} includes the worker's walking time from Station i to Station j , and the setup time for the machine (or station) j , which is required before processing of a job can start at Station j . Switchover times are negligible in lines where stations are close to each other and they do not require setup; or if they do, the setup times are negligible compared to processing times.

We model processing times at Station i as a random variable S_i with mean of $E[S_i]$ and we consider a case in which jobs are released randomly to Station 1 according to a Poisson process with rate λ jobs per unit time. The line would be a stable line if job release rate λ is less than the maximum capacity of the line, which is $1/(E[S_1] + E[S_2])$. Stability condition $\lambda < 1/(E[S_1] + E[S_2])$ guarantees that the average WIP in the line will not grow to infinity. The question we investigate here is as follows: for a given job release rate λ in a stable system, what is the worker control policy that minimizes the WIP and cycle time in this line?

The answer is quite simple. The optimal worker control policy is a pick-and-run policy (PR) [8], as follows:

Pick-and-Run (PR) Policy. Under a PR policy, a worker finishes one job by processing it at all stations in the line

consecutively, before starting to process the next job at Station 1.

If one considers holding cost h_i for a unit of WIP per unit time at Station i , this policy has been shown to also minimize the total expected holding cost in the system, if $h_2 \geq h_1$ [9]. Note that condition $h_2 \geq h_1$ holds in practice; since operations at Station 1 add value to jobs, the WIP at Station 2 is therefore more valuable than that at Station 1. It has been shown that the PR policy also minimizes WIP and cycle times in one-worker push lines with more than two stations and zero switchover times.

Single-Worker Lines with Switchover Times and Costs. When the switchover time D_{ij} and/or the switchover cost K_{ij} associated with worker switches from station i to j are not zero,³ the optimal worker control policy becomes more complex. For example, consider the above two-station push line with one fully cross-trained worker. If switchover times D_{12} and/or D_{21} are not zero, then the simple PR policy does not always minimize the WIP or cycle time in the line.

For this two-station line, the optimal worker control policy that minimizes the expected holding and switching costs if $h_2 \geq h_1$ is a simple greedy and exhaustive policy at Station 2, but it has a very complex structure at Station 1 [9]. Note that when $h_1 = h_2$ and $K_{ij} = 0$, this policy also minimizes the WIP and cycle time in the line.

Greedy and Exhaustive Policies. When a worker arrives at a station, under a greedy policy the server never idles in that station, and under an exhaustive policy the worker processes jobs in that station until the station becomes empty, whereupon the worker switches to another station.

Thus, under the optimal worker control policy, when the worker switches to station

³See Ref. 10 for examples of systems with switchover costs.

2, regardless of the WIP accumulation (due to job arrival) at Station 1, the worker processes all jobs at Station 2 until that Station becomes empty; only then does the worker switch to Station 1. In contrast to the exhaustive policy at Station 2, which is independent of the WIP levels at Station 1 and 2, the optimal worker control policy at Station 1 has a very complex dynamic structure that depends on the WIP levels at both stations. This policy is not easy to implement in practice. The following triple threshold (TT) heuristic policy is, however, easier to implement than the optimal policy, and has also been shown to result in a cost very close to that obtained under the optimal policy.

According to the TT policy, when the worker switches to Station 1, she starts processing jobs in that station only if the number of jobs in that station is at least M_w ; otherwise, she waits there until the number of jobs reaches that limit. When the worker does start processing jobs at Station 1, she does not switch to Station 2 until either M_n ($M_n \geq M_w$) jobs are completed without interruption, or Station 1 becomes empty and there are at least M_e jobs at Station 2 ($M_w \leq M_e \leq M_n$), whichever occurs first.

The stability condition in the push line under the TT policy is $\rho + \eta/M_n < 1$, where $\rho = \lambda(E[S_1] + E[S_2])$, and $\eta = \lambda(E[D_{12}] + E[D_{21}])$.

For systems with both switchover times and switchover costs, there exists no close-form solution for the best values for M_n , M_w , and M_e that minimize the total expected holding and switching costs. These values can be obtained through search algorithms using either a complex queueing model [9] or a computer simulation. However, for systems with only switchover costs (and zero switchover times), an efficient and robust policy can be easily obtained. Zero switchover times represent situations where the workstations are close to each other (i.e., worker walking times are negligible), and setup times are reduced significantly by performing the majority of setup operations off-line [11,12]. Thus, lines with zero switchover times but nonzero switchover costs represent situations where the workers' switching times (due to on-line machine

setup times) have been reduced to insignificance in comparison with processing times; however, there exist switching costs that represent costs associated with off-line setup operations.

For our two-station push line with switchover costs (and zero switchover times) and $h_2 \geq h_1$, the optimal worker control policy is still greedy and exhaustive at Station 2. However, the following simple heuristic policy, called *limited policy with start-up batch* (LPSB), has been shown to be very close to optimal and easy to calculate.

LPSB. According to LPSB, when a worker arrives at a station, she/he remains idle until the number of jobs in that station reaches M_s . The worker then starts processing jobs until either that station becomes empty or at most M ($M > M_s$) jobs are processed, whereupon she/he switches to another station.

The key aspect of this heuristic is that the best values for its parameters M and M_s can be easily obtained using only the first moments of stochastic processing and inter-arrival times. For example, the best value for M —namely M^* —is an integer that satisfies

$$\begin{aligned} & \frac{M^*(M^* - 1)}{2} \\ & \leq \frac{K_{12} + K_{21}}{h_2(E[S_1] + E[S_2]) + h_1(E[S_1] + 1/\lambda)} \\ & \leq \frac{M^*(M^* - 1)}{2}. \end{aligned}$$

The best value for M_s can also be obtained through a simple algorithm that uses only average job processing times $E[S_i]$ and job release rate λ [10].

Note that the main difference between the optimal worker control policy in lines with switchover times (and/or costs) and in lines without either is that in lines with switchovers, the worker does not switch to another station until a batch of jobs is processed. For example, under the LPSB policy, the worker processes a batch of size m ($M_s \leq m \leq M$) before switching to another station.

The optimal worker control policies in lines with switchover times and/or costs become very complex as the number of stations in the line increases. Those policies dictate complex batching policies, which depend on the WIP levels in each station in the line. For worker control policies in single-worker N -station lines with switchover times and costs [13–16].

Single-Worker Push Lines with Automated Machines. All push lines presented so far consist of stations in which processing a task requires the constant presence of a worker during the entire operation. We refer to these as *worker-based production environments*. Such environments are usually found in systems in which processing a job requires simple tools or nonautomated machinery. In production systems with automated machinery, however, processing a job on a machine typically requires four basic operations in the following sequence: (i) loading, (ii) setup, (iii) machine processing, and (iv) unloading. In general, the worker must be present for loading, setup, and unloading, but not during processing, which is automated. We refer to production environments with this type of equipment as *machine-based environments*. Although manufacturing cells are usually machine-based environments, most of the literature on cellular manufacturing with cross-trained operators formulate these systems as worker-based environments by assuming (explicitly or implicitly) that the worker must supervise or control the machine during processing. Reviews of this research can be found in Refs 17 and 18.

Machine-based environments present more opportunities for worker cross-training, since workers will be idle during the automatic processing times. On the other hand, worker control policies in worker-based environments are not applicable to machine-based environments. For instance, consider a single-worker two-station push line with an automatic machine at Station 1. Suppose that the operation on the automatic machine requires a loading (done by the worker) and an automatic processing (that

does not require any worker presence).⁴ As is true in practice, suppose that a worker cannot load a new job on the machine when the machine is processing a job.

We showed that in one-worker two-station push lines without automatic machines (for systems with or without switchover times or costs), the optimal worker control policy requires that after a worker switches to Station 2, he does not switch back to Station 1 (regardless of the WIP level at Station 1) until all jobs at Station 2 are processed (i.e., a greedy and exhaustive policy). With an automated machine at Station 1, however, this policy is no longer optimal.

For a system with Poisson job release and exponentially distributed task times (e.g., loading time at Station 1, and processing times at Stations 1 and 2), Hopp *et al.* [19] showed that the optimal control policy has the following properties: (i) When the machine is automatically processing a job at Station 1, the worker must switch to station 2 and work there, if Station 2 is not empty. (ii) When the machine is not processing a job, the decision on whether to work at Station 2 or to load a new job on the automated machine at Station 1 has a complex monotone structure that depends on the WIP levels at both Stations 1 and 2. When the automated machine is at station 2, however, the optimal worker control policy becomes simple: it is a fixed-priority policy, which always gives priority to loading the machine at Station 2. Only when the machine at Station 2 is processing a job, or if Station 2 is empty does the worker work at Station 1.

The optimal worker control policy becomes more complex in longer lines with more than one automated station. This makes the optimal worker control policy difficult to implement in practice. Thus, the following two-worker control policies are preferred in Hopp *et al.* [19] as easy to implement policies⁵:

⁴Unloading times are insignificant and setup is considered as a part of loading operations.

⁵For the stability condition under fixed-priority and cyclic policy, see Ref. 19.

Fixed-Priority Policy. The fixed-priority policy is a static priority policy under which the worker attends stations in a fixed order. The order specifies stations from the highest priority to the lowest. When the worker arrives at a station, she/he works at that station until she/he becomes idle (due to the station becoming empty or the automated machine being loaded, if the station is an automated station); she/he then switches to the next lower-priority station. If a job becomes available at a higher-priority station (e.g., when an automated machine finishes processing and requires unloading), the worker interrupts her/his work at the current station and immediately switches back to the higher-priority station.

Cyclic Policy. Under a cyclic policy, the worker attends workstations in a cyclic fashion. When the worker arrives at an automated station, she/he waits for the machine to finish processing the current job (if it is not yet finished), then unloads the processed job, loads the new job onto the machine, switches the machine on, and then carries the previously completed job to the next station. If the worker arrives at a manual station, she/he processes the job at that station. If the worker arrives at a station with no jobs, she/he immediately moves on to the next station in her cycle.

In a simulation study performed by Hopp *et al.* [19] of one-worker three-station push lines with one, two, or three automated stations, in which the automated machines required loading, automatic processing, and unloading operations to complete a job, it was observed that the performance of the best fixed-priority policy is always better than the performance of the best cyclic policy. Also, it has been shown that when the best fixed-priority policy is adopted, automating a station at downstream is more effective than upstream automation. In contrast, when the best cyclic policy is adopted, upstream automation is more effective than downstream automation. If one station is to

be automated in a single-worker push line, then placing automation downstream and using the best fixed-priority policy results in the lowest WIP and cycle time in the line, all other things (e.g., costs) being equal.

Multiple-Worker Push lines

One of the features of shojinka is its flexibility in adjusting the throughput of a line by changing the number of workers in the line. When demand is high, the number of workers is increased, resulting in lines with multiple (cross-trained) workers. When more than one worker can work at a given station, this creates two different kinds of environments for us to consider: (i) a *collaborative environment* in which workers can work together as team on one job, so the job can be finished faster; and (ii) a *noncollaborative environment*, in which workers cannot collaborate, although they can work independently on different jobs in a station. In this section we present some design and control principles for both collaborative and noncollaborative environments in multiple-worker push lines

The collaborative environments that we discuss in this article are those in which collaboration is *additive*. Specifically, when w workers work together on a single job, then the job completion has a rate of $\mu_1 + \mu_2 + \dots + \mu_w$, where μ_j is the job processing rate of Worker j if she/he processes the job by herself/himself.

Collaborative Environments. To start, consider a simple two-station line with two fully cross-trained workers who can work at both stations. Suppose that the processing times at Stations 1 and 2 are exponentially distributed with rates μ_1 and μ_2 , respectively. Jobs are released randomly to Station 1 according to a Poisson process with rate λ . There are holding costs h_i per job per unit time for jobs at station i , but the switchover times and costs are zero. Also, workers can preempt (i.e., interrupt) processing a job at one station to work on another job at a different station.

Consider a collaborative environment in which Workers W1 and W2 can work on a single job at station i ; the average job processing time is therefore shortened by half,

that is, the processing rate in that station is doubled to $2\mu_i$. In this case, the optimal worker allocation policy has a very simple structure [20]. If $\mu_1(h_1 - h_2) \geq \mu_2 h_2$, then the optimal worker control policy is exhaustive at Station 1. An exhaustive policy at Station 1 assigns both workers to Station 1 until it becomes empty; both workers then switch to Station 2. While working on Station 2, if a job becomes available at Station 1, both workers interrupt their work at Station 2 and switch to Station 1 immediately. On the other hand, if $\mu_1(h_1 - h_2) \leq \mu_2 h_2$, then the optimal policy is exhaustive at Station 2; this means that both workers work together on a single job at Station 1, and then switch to Station 2 to finish the processing of that job. They then switch back to Station 1 and start working together on a new job. This policy is also called an expedite policy for a collaborative environment:

Expedite (EX) Policy. Under an expedite policy all workers work on a single job at all consecutive stations until the job is processed at the last station. All workers then start working on a new job at Station 1.

Note that when $h_1 = h_2$, the objective of minimizing the expected holding cost becomes equivalent to minimizing the expected WIP in the line. On the other hand, when $h_1 = h_2$, the optimal worker control policy in two-station Markovian lines⁶ with two workers is the expedite policy (since $0 = \mu_1(h_1 - h_2) \leq \mu_2 h_2 = \mu_2$). In fact, Van Oyen *et al.* [8] show that while minimizing WIP or cycle time is the goal in a collaborative environment, the expedite policy is also optimal in longer lines with N stations ($N \geq 2$) and W workers ($W \geq 2$) and with generally distributed job processing times, as long as the switchover times and costs are zero.

⁶Markovian lines are lines in which event times (e.g., processing times, job interarrival times) are exponentially distributed.

Noncollaborative Environments. In noncollaborative environments, however, things are different.

Consider the above two-station line in a noncollaborative environment. It has been shown that condition $\mu_1(h_1 - h_2) \geq \mu_2 h_2$ is only a sufficient condition for the optimality of the exhaustive policy at Station 1; but when $\mu_1(h_1 - h_2) \leq \mu_2 h_2$, there is no guarantee for the optimality of the exhaustive policy at Station 2 [20]. For these cases, one can use a push/pull heuristic worker control policy. According to a push/pull policy, one worker is assigned to each of the two stations. Each worker works in his/her station until there is no work available there, whereupon the worker switches to the other station and works there until a job becomes available at his/her original station. A push/pull heuristic is shown to perform well in cases where the sufficient condition for the optimality of an exhaustive policy at Station 1 does not hold.

The optimal worker control policy in longer lines with more than two workers is even more complex. For an N -station line with W fully cross-trained workers and zero switchover times and costs, it has been shown that the PR policy, while not necessarily optimal, is an effective worker control policy in noncollaborative environment [8]. Under PR policy each worker works sequentially (and independent of other workers) in consecutive stations 1 to N .

Lines with Switchover Times. In lines with nonzero switchover times and/or costs, the PR or EX policies may not be optimal. As shown in one-worker lines, the existence of a setup time (or cost) calls for worker control policies that impose lower and/or upper bounds on the number of jobs (i.e., batch size) processed in a station. Furthermore, like push lines with stochastic arrivals and/or job processing times and nonzero switchover times, the stability of the line depends on the worker control policy (e.g., stability under a TT policy depends on M_n). Thus, the key issues in lines with switchover times are (i) finding what the maximum capacity (throughput) of the line is, and (ii) determining the worker control policies that can achieve the maximum capacity with lower WIP levels.

Andradóttir *et al.* [4] investigate these questions in an N -station push line with switchover times and with W cross-trained workers such that each worker is cross-trained to work on at least one station, and each station has at least one worker who is trained to work there. Job interarrivals and process times as well as worker switchover times are stochastic. Using a deterministic LP model for the flow maximization in the line (i.e., capacity balancing), they obtain a tight upper bound on the maximum capacity (i.e., throughput) of the line, as well as the fraction of time each worker needs to spend at each station to achieve that capacity. They also show that the amount of cross-training needed for achieving maximal capacity is $M + W - 1$ skills (out of a total of MK skills which when all workers are fully cross-trained).

Consider these multiple-worker push lines with switchover times in a nonpreemptive environment in which once a worker starts processing a job, it cannot be stopped until the job is completed. The following *generalized round-robin* (GRR) policy is shown to achieve a capacity (i.e., throughput) arbitrarily close to the maximum capacity.

GRR Policy for Noncollaborative Environments. Under a GRR policy, each Worker j visits the set of stations $\mathcal{V}_j$ in cyclic order. When the worker arrives at station $k \in \mathcal{V}_j$, the worker starts processing jobs at that station until $M_j^{(k)}$ jobs are served, or the worker becomes idle, whichever occurs first; the worker then switches to the next station in $\mathcal{V}_j$ (i.e., an LPSB with $M = M_j^{(k)}$ and $M_s = 0$). If Worker j has no job to process (because either all stations in set $\mathcal{V}_j$ are empty or all available jobs in that set are being served), then she/he idles.

For collaborative environments, the above GRR policy is replaced with the following policy that uses time-based thresholds rather than WIP-based thresholds for workers' movements.

GRR Policy for Collaborative Environments. Under a GRR policy, each

worker j visits the set of stations $\mathcal{U}_j$ in cyclic order. When the worker arrives at station $k \in \mathcal{U}_j$, she/he works at that station for $T_j^{(k)}$ units of time. If Station k empties before this occurs, then the worker switches to the next station in $\mathcal{U}_j$. If the worker is still working on a job when this occurs, the worker switches to the next station after completing that job. If Worker j has no job to process (because either all stations in set $\mathcal{U}_j$ are empty or all available jobs in that set are being served), then she/he idles.

For the cases of both collaborative and noncollaborative environments, Andradóttir *et al.* [4] developed an algorithm that obtains the parameters of the GRR policies (i.e., $\mathcal{V}_j$, $M_j^{(k)}$, $\mathcal{U}_j$, and $T_j^{(k)}$ for all $j = 1, 2, \dots, W$) that guarantees achieving a desired throughput.

Although the GRR policies are designed to achieve a particular throughput, they have enough flexibility to be designed for secondary considerations as well, such as lowering the WIP in the line. For systems with both high variability in the service and/or interarrival times and small values for switchover times, smaller values of WIP may be attained by lowering parameters $M_j^{(k)}$ and $T_j^{(k)}$, as appropriate.

PULL LINES WITH FLEXIBLE WORKERS

In contrast to a push protocol under which jobs are released to the line independent of the WIP level in the line, the release of new jobs under a *pull* protocol depends on the status (i.e., WIP levels) in the line. For example, under a CONWIP (CONstant Work-In-Process) pull protocol, a new job is released to the beginning of the line only when a job has been completed and has left the end of the line [7]. In pull systems, limited WIP (which can be enforced using limited buffers in the line or by other means) may cause blocking or starvation of a station in the line, which in turn reduces the throughput of the line. Thus, as opposed to push lines in which the throughput is given (i.e., it is equal to the job release rate in a stable line) and the objective is to minimize WIP, in pull lines

the maximum WIP is given and the objective is to design and control the line so that the throughput of the line is maximized.

CONWIP Lines with Flexible Workers

Consider an N -station pull line with W fully cross-trained workers and no limit on the buffer sizes at each station, and suppose that the line is run under CONWIP pull protocol. It has been shown that, if the processing times of the jobs in each station are exponentially distributed, then the EX policy maximizes the throughput of the line in *collaborative* environments with fully cross-trained workers. Of course, since all workers under the EX policy work together on a single job, the constant WIP level of one is enough for the CONWIP line to reach its maximum throughput. In *noncollaborative* environments, however, the PR policy has been shown to be optimal, when the minimum constant WIP level required to reach the maximum throughput is equal to W , that is, equal to the number of workers in the line [8].

One of the common cross-training practices is to cross-train workers assigned to nonbottleneck stations so that (if needed) they can also work in bottleneck station(s). This often results in some (but not all) of the workers being cross-trained for just some of the stations, that is, becoming *partially* cross-trained workers. The worker control policy for lines with fully cross-trained workers may not be effective or even feasible in lines with partially cross-trained workers.

As an example, consider a simple two-station CONWIP line with two workers and zero switchover times in which the average processing time at Station 1 is larger than that at Station 2; Station 1 is therefore the bottleneck. Suppose that Worker W1 is assigned to Station 1, and Worker W2 to Station 2. Worker W2, however, is also cross-trained to work at Station 1. The worker control policy, of course, only concerns Worker W2, since Worker W1 is not cross-trained. Gel *et al.* [21] show that under the optimal control policy, Worker W1 will never idle as long as there is at least one job at Station 1, and Worker W2 will never idle as long as there is at least one job at Station 2. Also, Worker W2 will not switch to

Station 1 as long as there is at least one job at Station 2. Worker W2 may, however, idle at Station 2 (and not switch to Station 1) when Station 2 is empty. On the other hand, if job processing times at Stations 1 and 2 are exponentially distributed, then it becomes optimal that Worker W2 switch to Station 1 immediately after Station 2 becomes empty.

The reverse of the above policy is also true, namely, when Station 2 is the bottleneck and only Worker W1 in Station 1 is cross-trained to work at the bottleneck Station 2. These results point to the principle that a cross-trained worker should give priority to processing the task(s) that he/she is uniquely qualified for before helping other workers out. This is called the *fixed-before-shared principle* in Gel *et al.* [21].

CONWIP Lines with Automated Machines

As shown in section titled “Single-Worker Push Lines with Automated Machines,” automating a station in a push line makes the worker control policy complex. It is interesting to study how automating a work station in a CONWIP line impacts the worker control policy in that line. Consider, for example, a three-station CONWIP line with one fully cross-trained worker, and assume that, without loss of generality, Station 1 is automated. Specifically, operations at Station 1 require loading a job on the automated machine, and automatic processing of the job by the machine (which does not require the presence of the worker). The processing at Stations 2 and 3 are manual and are performed by a single worker. Also, suppose that the worker can interrupt her tasks and switch to another station, if necessary (i.e., preemption is allowed).

Assuming exponentially distributed times for loading, as well as for both automatic and manual processing, Hopp *et al.* [22] show that the optimal worker control policy in this three-station line is a *fixed-priority policy*, which assigns the highest priority to the automated station and the second highest priority to the station that feeds the automated station. Specifically, under the optimal worker control policy, the worker first checks Station 1 (the automated station), and loads it if there is a job and the machine is not

automatically processing. She/he then checks Station 3, which directly feeds Station 1, and works there if a job is available; otherwise, she/he processes a job at Station 2, if there is any. The worker idles only when none of the above conditions is satisfied. Comparing this policy with the optimal control policy in a one-worker push line, we can easily see that the control policy in the CONWIP line is much simpler and thus easier to implement in practice.

By examining a fixed-priority policy and a cyclic policy in a simulation study of three- and five-station single-worker lines with one or more automated stations, Hopp *et al.* [22] show that, as opposed to push lines, which benefit from putting automation in downstream, the location of automation does not have a significant impact on the performance of a CONWIP line. They also identified other benefits of single-worker CONWIP lines over their push counterparts, such as efficiency, robustness, and design flexibility.

Finite Buffer Pull Lines with Flexible Workers

Now consider an N -station line with fully cross-trained workers in which, the WIP in the line is limited not by using a CONWIP protocol, but by limiting the size of the buffer at each station. Specifically, suppose that the buffer (downstream) of Station i in the N -station line can hold a maximum of B_i jobs. Also, suppose that there are always ample jobs available at the buffer of Station 1 (so Station 1 never starves), and the completed jobs at Station N depart the system immediately (so Station N is never blocked). Let the average processing time at each station be $1/\mu_i = 1$ (i.e., the line is balanced), but suppose that workers have different speeds. Specifically, if Worker j works at Station i , the average time to finish the job at that station is $1/\mu_{ij}$. A worker at Station i is blocked, if after completion of a job at Station i , she/he finds the upstream buffer at Station $i + 1$ full (i.e., production blocking).

Note that, in general, the limited buffer sizes in the line and the variability in processing times result in nonzero probability that stations are blocked or starved, which in turn results in lower throughput. Thus, the worker control policy in these lines plays an

important role in maximizing the throughput of the line. It has been shown that in two-station Markovian lines in collaborative environments with two fully cross-trained workers, the optimal worker control policy is to assign both workers to Station 1 when Station 2 is starved, and to assign both workers to Station 2 when Station 1 is blocked. Otherwise, the optimal control policy is to assign Worker W1 to Station 1 and Worker W2 to Station 2 if $\mu_{11} \mu_{22} \geq \mu_{21} \mu_{12}$, or Worker W1 to Station 2 and Worker W2 to Station 1 if $\mu_{11} \mu_{22} \leq \mu_{21} \mu_{12}$ [23].

For longer lines with $N \geq 3$ stations and the same number of fully cross-trained workers as stations ($N = W$), one extension of the above policy is as follows.

Primary Assignment. Assign Worker i to Station $j_i \in \{1, 2, \dots, N\}$ such that exactly one worker is assigned to each station and $\prod_{i=1}^M \mu_{ij_i}$ is maximized.

Contingency Plan. At any time when Station $j \in \{1, 2, \dots, M\}$ is *blocked*, the server assigned to Station j will be working at the nearest nonblocked downstream Station k ($k > j$). At any time when Station j is *starved* (but not blocked), the server assigned to that station will be working at the nearest nonstarved upstream station k ($k < j$).

If all workers have the same speed at each station (i.e., $\mu_{ij} = \mu_i$ for all $j = 1, 2, \dots, N$), and processing times are exponentially distributed, the EX policy is optimal.⁷ Note that the Ex policy achieves the maximum throughput with the minimum WIP level in the line, that is, one. However, when one or more workers are faster than others in some stations (i.e., some workers are specialized on some tasks in the line), then the Ex policy is not optimal. It has been shown that

⁷Recall that when all workers have the same speed in each station of the line, the Ex policy maximizes the throughput of the line in a collaborative environment under a CONWIP protocol with only one unit of WIP. Since in a line with finite buffers each station has the capacity of holding at least one job, the Ex policy will also be optimal in those lines.

in those cases, the above heuristic achieves higher throughput than the Ex policy. This was observed through a simulation study of three- and five-station lines [23].

Bucket Brigade Lines

Bucket brigade lines are N -station lines with W fully cross-trained workers, where $W < N$. These lines are motivated by the TSS (Toyota Sewn Products System), where there are more stations than workers. In TSS lines, workers are cross-trained to do all tasks within a zone of consecutive stations, and possibly for the entire line.

The worker control policy in bucket brigade lines, which is for lines in non-collaborative environments, is based on numbering workers from 1 to W according to their sequence in the line (in the direction of product flow). Each worker then follows the following forward and backward rules.

Forward Rule. Each worker should process a job in successive workstations, where at any station, the worker with a higher index has priority. If the job is taken over by the worker's successor, then the worker should relinquish the job and begin to follow the backward rule. If the worker is the last worker in the line (i.e., Worker W) and completes the job at the last station, she/he must relinquish the job and begin to follow the backward rule.

Backward Rule. The worker should walk back and take over the job of his/her predecessor. If the worker is the first worker in the line, the worker should walk back and pick up the raw material to start a new job at Station 1. The worker should then follow the forward rule.

Note that under the bucket brigade control policy, Worker i is always between worker $i - 1$ and $i + 1$ in the line. Even if Worker i is faster than Worker $i + 1$, she/he never passes Worker $i + 1$, because the bucket brigade policy requires that her job be handed off to Worker $i + 1$. Furthermore, in bucket brigade lines, there is always a constant WIP level

of W jobs in the line, since each worker is working on only one job at any time.

Bucket brigade lines have been shown to work effectively in environments in which (i) walking and handoff times are insignificant, (ii) each worker $i = 1, 2, \dots, W$ is characterized by a distinct, constant work velocity, and (iii) the nominal work content of the product is a constant (i.e., deterministic) and the work content is spread continuously and uniformly along the flow line. It has been shown that in such an environment, the maximum throughput of the line is achieved by arranging the workers in increasing order of their work speed, that is, by making the slowest worker be first in the line, and the fastest be last. Furthermore, under the slowest-to-fastest sequencing scheme, the line balances itself (see Ref. 24 for details). A bucket brigade line is called *balanced* if each worker repeats the same interval of work content on successive jobs. A balanced line produces at a steady rate and each worker (although fully cross-trained) ends up working on only a subset of the work content. Further studies on bucket brigade lines have shown that these lines also perform relatively well in some cases where processing times are stochastic and work content is discrete along the line [25,26; and references therein].

However, when the variability in process times is not low, and when the differences in workers' speeds are not significant, a bucket brigade control policy performs poorly. This is because, under these circumstances, substantial idle time occurs whenever workers catch up with their downstream coworkers, but are not allowed to pass them [27]. Nevertheless, bucket brigade lines have been shown to be very successful in order picking environments such as warehouses.

Finite Buffer Lines with Partially Cross-Trained Workers

As pointed out, cross-training all workers for all stations in the line is not always practical or economical. Therefore, many lines exist in practice whose workers are partially cross-trained to work only in their specified working zone. For each Worker i , a working zone Z_i is a set of consecutive stations in

the line for which the worker is cross-trained (or allowed) to work $Z_i \subseteq \{1, 2, \dots, N\}$. Note that working zones of workers may overlap, which means that there will be stations in the line for which more than one worker is responsible.

McClain *et al.* [27] performed an extensive simulation study of lines in noncollaborative environments with partially cross-trained workers, different worker speeds, different buffer sizes, different station-to-worker ratios, and different process time variability levels. The study investigates the impact on the throughput of the line on the sizes of the worker zones, the sequencing of the workers (slowest-to-fastest or fastest-to-slowest), and worker control policies.

For a wide range of lines with partially cross-trained workers and finite buffers, McClain *et al.* [27] show that the following WIP-based worker control policy is an effective one.

Half-Full Buffer. If the buffer between two stations i and $i + 1$ is below half-empty, workers work at Station i . If it is above half-full, workers work at station $i + 1$.

They also show that increasing the machine-to-worker ratio improves efficiency by giving workers more opportunity to keep busy without interfering with each other. (See Ref. 27 and references therein for more details.)

Implementation

Although there might be several worker control policies that could be implemented in a production line, one should be careful when choosing among them. The decision as to which worker control policy to adopt in practice depends on the task itself and the characteristics of the environment. These characteristics include training efficiency, switching efficiency, preemption efficiency, and collaboration efficiency [2].

Training efficiency represents how effectively workers can be cross-trained for different tasks. Factors that affect training efficiency are the cost of training, the difficulty of the tasks, and the impact of cross-training on quality. *Switching*

efficiency corresponds to how effectively a cross-trained worker can switch from one task to another. Examples of environments with low switching efficiency are lines with long walking times between work stations, and/or long setup times between two tasks. *Preemption efficiency* is concerned with how effectively one worker can take over the job of the original worker, while the original worker is still processing that job. Preemption efficiency is affected by such factors as breaking the rhythm of the workers, the need for information exchange when an incomplete job is handed off to another worker, and the possibility of quality problems due to a handoff. Finally, *collaboration efficiency* corresponds to how collaboration among workers in teams can improve performance, such as by increasing throughput or improving quality. For example, it is critical to know whether two workers who work as a team can finish a task more than twice as fast as when each works independently, or whether they can produce a better quality product as a team.

All of these environmental factors should be considered in choosing a worker control policy. For example, for environments in which training efficiency is high and switching efficiency is low, it would be appropriate to choose XP and PR policies. This is because, in order to use XP and PR policies, all workers must be cross-trained for all tasks and all workers must switch among all stations. Moreover, for the XP policy in particular, the collaboration efficiency should also be high. On the other hand, choosing a bucket brigade policy would be appropriate in an environment in which the two most critical environmental factors are training efficiency and preemption, and especially in environments where work content is continuous (e.g., order picking). And GRR policies are best suited for environments where switching efficiency is high; in this case, the collaboration efficiency must also be high if jobs are processed in teams.

DESIGN OF CROSS-TRAINING STRUCTURES

In the previous sections, we focused primarily on the worker *control* principles for some

given cross-training structures in push and pull lines. A higher strategic level decision is how to *design* worker cross-training structures (i.e., how to decide which worker should be cross-trained for which task) to achieve maximum performance.

As mentioned in the introduction, cross-training can significantly improve a system's performance through capacity balancing. Thus, the first property of an effective cross-training structure is that it should balance capacity. As described in section titled "Capacity Balancing", cross-training structures that can balance capacity can be obtained using simple LP models (see [4–6], and references therein).

Often, more than one cross-training structure can achieve capacity balancing. The decision as to which one to choose then depends on both monetary considerations such as costs of cross-training and environmental factors such as the maximum number of workers who can work at a station or on a job at any one time. For example, a structure in which all workers are cross-trained for all tasks can balance all pull and all stable push lines. However, it has a very high worker training cost; moreover, it is usually not feasible in practice for all workers to work at one station.

If more than one structure can balance capacity and satisfy system constraints, then the decision as to which structure to choose depends on the effectiveness of those structures in buffering variability. For example, consider a CONWIP line with four stations and four workers, and suppose that the average processing times at Stations 1, 2, 3, and 4, are 1, 0.6, 1, and 0.6 min, respectively. Figure 2 shows two possible cross-training structures that can balance capacity in this line. In Fig. 2a, both Workers W1 and W2 are cross-trained to work at Stations 1 and 2, while both workers W3 and W4 are cross-trained to work at Stations 3 and 4. In Fig. 2b, however, Worker W1 is cross-trained for Stations 1 and 2, Worker W2 for Stations 2 and 3, Worker W3 for Stations 3 and 4, and Worker W4 for Stations 4 and 1.

The structures in Fig. 2 are similar in many aspects. In both structures each worker is trained to work at two stations (i.e., cost of

cross-training is the same in both structures), and each station is attended by a maximum of two workers. Also, both structures balance the capacity of the line.⁸ The question is therefore which of these two structures provides better performance against variability, and thus results in a higher throughput for the line.

Using simulation for lines with different WIP and variability levels, [28] show that the structure in the first case of Fig. 2b results in a throughput that can be significantly higher than that in 2a. This example shows that cross-training structures that balance capacity and have similar properties (e.g., the same total number of skills, the same number of skills per worker) may result in significantly different performance. This implies that the variability buffering feature of cross-training structures should be considered in designing cross-training structures.

If used under the appropriate worker control policy, the full cross-training structure has the most flexible capacity balancing and the most effective variability buffering features. As mentioned, however, the bad news is that full cross-training may not always be practical or economical. The good news, on the other hand, is that in some situations, some partial cross-training structures exist, which can achieve a performance close to that of the full cross-training structure. One of these structures is the structure in Fig. 2b which is called a *two-skill chain* structure. The concept of a chain structure was first introduced by Jordan and Graves [28] for assigning products to factories. In the context of worker cross-training, the two-skill chaining structure in an *N*-Station line is defined as follows.

Two-Skill Chaining. Under a two-skill chain, the number of workers and the number of work stations are the

⁸Note that processing times at Stations 1 and 2 are the same as those in our two-station line example in section titled "Capacity Balancing." The same is true for Stations 3 and 4. Thus, capacity balancing in Fig. 2 is analogous to that for the two-station line in section titled "Capacity Balancing."

Figure 2. Two cross-training structures for a U-shaped four-station CONWIP line with four workers.

same, and each Worker i is cross-trained to work in Stations i and $i + 1$ ($i = 1, 2, \dots, N - 1$), while Worker N is cross-trained to work in Stations N and 1. This creates a chain of skills (work zones) that overlaps by only one station.⁹

After this skill chaining principle was introduced, many researchers studied the properties of skill chaining structures in supply chain design, call center agent cross-training, repairman cross-training, and worker cross-training [5,6,29–33], among others. These studies have led researchers to the following general conclusions: (i) *efficiency*: skill chaining cross-training structures capture the majority of the benefit of full cross-training structures, (ii) *robustness*: skill chaining structures are robust with respect to changes in the environment (e.g., a temporary change in workload, or changes in variability) and in worker control policy.

Note that under a full cross-training structure, all workers can directly help each other and, if needed, all workers can even work at

one station. The efficiency and robustness of skill chaining structures are due to the fact that, while only a maximum of two workers can work at each station, nevertheless all workers can also directly or *indirectly* help each other when needed [6].

In conclusion, the question of which cross-training structure is the most effective among all capacity balancing structures is not easy to answer. This is because the underlying queueing model of systems with cross-trained workers is a complex queueing system in which, not only jobs, but also servers move among queues. Thus, a computer simulation is often needed to evaluate and compare the performances of different cross-training structures. Iravani *et al.* [6], however, introduce the concept of *structural flexibility* and develop *structural flexibility metric* that can be used to choose the most effective structure among all capacity balancing structures. This metric is obtained by simply solving a deterministic max-flow problem established based on the bipartite graph of cross-training structures. This heuristic method is then shown to be very effective in choosing the most effective cross-training structures in serial and parallel job processing systems such as production lines and call centers. Iravani *et al.* [34] further extend this metric to include

⁹For a more general definition of a D -skill chain structure [6].

cases where resources (e.g., workers) have different speeds.

CONCLUSION

The design and control of manufacturing systems with a flexible (cross-trained) workforce are significantly more difficult than the design and control of traditional manufacturing systems. This article has presented design and control principles for serial production lines with flexible workers. It has shown how cross-training can improve performance through capacity balancing and variability buffering. It has also described how different manufacturing practices (e.g., push and pull), automation, operations characteristics (e.g., setup times and costs), and task nature (collaborative or noncollaborative) impact the decision as to how each worker should allocate her/his time among stations for which she/he is cross-trained. Although the optimal worker control policies are usually too complex to be used in practice, cost-effective heuristic policies, can often be found, which are simple and thus easy to implement.

The design of worker cross-training structures (i.e., deciding which worker should be cross-trained for which task) is also a difficult task. This is because manufacturing systems with cross-trained workers are complex queueing networks in which, not only jobs, but even servers move among queues. An efficient design must not only balance capacity, but also satisfy physical and environmental constraints. While full cross-training structures can effectively balance capacity and buffer variability, they are often neither economical nor practical in lines with large number of stations. In contrast, chain cross-training structures, which require less worker training, have been shown to capture the majority of the benefit of full cross-training structures. They are also reasonably robust with respect to changes in the environment.

Knowledge about products and their sub-assemblies regarding location, status, physical integrity, environment conditions and identity in the supply chain at any given time is of great economic value to stakeholders. For instance, according to the US Department of Agriculture's Food Safety and Inspection Service [1], on May 14, 2010, Sampco, Inc. recalled 87,000 pounds of beef products that may contain the animal drug Ivermectin; the next day, Montclair Meat Co., Inc. recalled 53,000 pounds of ground beef products that may have been contaminated with *Escherichia coli* O157 : H7, a deadly bacterium. Every year, the US Consumer Product Safety Commission has notified several hundred recalls in the United States, which have incurred extraordinary financial consequences. In order to track product production and distribution, so that recalls can be controlled or targeted, it is necessary to manage supply chains with tracking systems [2]. Such systems provide visibility, traceability and associated information throughout different stages of a supply chain. The rationale behind an effective tracking system includes efficient operations, product safety and security, obsolescence and shrinkage reduction, responsiveness to the market and recovery of items, which makes a supply chain tracking system imperative. However, there are several challenges to design an effective tracking system.

First of all, the continuing momentum towards globalization and a multi-layer outsourcing policy stretches supply chains across geographic and cultural boundaries, leading to longer chains [3]. As more parties in different locations are involved in one supply chain, there is a surge in the complexity of coordination and operation. Tracking the entire supply chain and designing the tracking system in a cost-effective way become increasingly difficult to achieve.

Secondly, there are various identification, communication and IT technologies available in the market, which are evolving rapidly. On top of this, some technologies have different standards to fit into a specific industry sector and operation environment. It is natural to infer that it will be a tough decision to pick up the right technology at the right level following the proper standard in order to better support the purpose of a tracking system.

Thirdly, a supply chain tracking system usually involves different IT systems. How to handle the information flow to align different interests in order to achieve information efficiency and security remains a challenge. The decision may depend on the industry sector, operation environment, and product characteristics, further complicated by the cost constraint. The answers to questions like when and where to post and retrieve information and how to facilitate the information exchange among multi-parties are still unclear.

In summary, various considerations in terms of technologies, standards, operations and strategies should be taken into account to design an effective supply chain. However, there are no complete design principles available at this moment. Some decision makers may obtain only partial guidelines, lose track of some inconspicuous but critical issues, and finally fail to fulfill the original goals. Others may invest exorbitant amounts in a tracking system with extra capacity, to resolve their problems. Therefore, it is the intent of this article to provide some feasible and practical guidelines to design an effective supply

chain tracking system in an economical way.

DESIGN CONSIDERATION OVERVIEW

Object identification (ID), data capturing, and exchange are the three main layers required to operate a tracking system, which could be illustrated by the EPCglobal architecture framework [4] in Fig. 1.

We elaborate the detail design considerations from the corresponding three aspects, ID system, reader infrastructure, and IT system in the section titled “Design Consideration for ID System,” “Design Considerations for reader infrastructure,” and “Design Considerations for IT system,” specified in Table 1. ID system considerations try to understand in what conditions to apply which ID technology and to which level in order to fit into a specific application environment. Reader infrastructure considerations relate to how to select readers to effectively capture information and communicate with the backend IT system and services. IT system considerations refer to how to exchange data efficiently.

DESIGN CONSIDERATIONS FOR ID SYSTEM

ID system considerations have two perspectives here, the first being how to choose a certain ID technology, including how to choose from (RFID) radio frequency identification and barcode, which are the two typical ID technologies for radio frequency (RF) and optical categories, respectively; and how to choose among various RFID tags. The second is what should be taken into consideration when applying the ID technology to a certain coding or packaging level.

ID Technology

RFID versus Barcode. On the basis of reports from inLogic Inc. and Atlas RFID Solutions [5,6], a brief comparison of the performance of RFID and barcode is summarized in Table 2. Basically, RFID is preferred when (i) the tag reading is required to be efficient, such as large reading speed and

range, non-line-of-sight and multi-reading; (ii) the tag is required to be rewritable, reusable or anti-counterfeiting; (iii) the operation environment is harsh such as requiring an ID label to be resistant to wear and tear, and to rough handling and inclement weather [7]; (iv) the labor cost is significant, as RFID can automate some operations and save labor costs [8]; (v) real-time information is required, as RFID enables continuous monitoring. If the tag performance could be compromised and cost is the critical consideration, barcode is competent. The choice under a specific application environment depends on the explicit estimation of the ID technology's value. It turns out to be the balance between more benefits due to RFID or less investment of barcode [9,10].

Choice Among Different RFID Tags. Different application areas and environments require RFID tags with different features and cost implications. Several important aspects are listed as follows:

1. *Operating Frequency.* There are basically three categories of RFID operating frequency: low frequency (LF), high frequency (HF), and ultra high frequency (UHF), with frequency less than 135 KHz, 13.5 MHz and 860–930 MHz, respectively [11]. From LF to UHF, the tag read range and rate increase, but the ability to read near metal or wet surface decreases. If the read range requirements are less than 1 m and do not require fast read speed, LF or HF may be an option; otherwise UHF is preferred. The application areas for LF and HF could be access control, payment ID, libraries, laundries, apparel; and that for UHF could be supply chain management, baggage handling, and electronic toll collection [11].
2. *Battery.* According to whether the device is battery powered or not, the RFID tag can be categorized as passive (no battery), semi-passive (battery assisted backscatter), and active (powered transmitter). Basically, if the application does not require a large read range (< 5 m) and long tag

Figure 1. EPCglobal standards architecture framework [4].

life time, passive tags are preferred. When choosing power assisted tags to achieve longer read range (10–100 m), several concerns deserve attention. Firstly, those tags are usually 7 to 10 times more expensive than passives ones due to the battery cost [12]. Secondly, recharging batteries may introduce operational complexity. For example, GreenOrbs is a long-term wireless sensor network system with more than 1000 nodes in the Tianmu forest in Zhejiang, China, for forest surveillance, fire risk evaluation, and

so on [13]. The battery recharge in a kilo-scale forest significantly challenges the system maintenance. Thirdly, the RF proliferation of the active transponders and battery discharge incur environmental hazards [12]. Therefore, it is important to develop the energy harvest technology and low-cost RFID circuit designs in order to fill the gaps of cost and energy consumption for power assisted tags.

3. *Environment.* It is important to select the tags with features that are aligned

Table 1. Overview of Design Considerations

ID System	Reader Infrastructure	IT System

Section: ID attaching level	Section: Reader networking	Section: Standardization

with the requirements of the use case [11]. If the operation environment is harsh, RFID tags need some special packaging; for instance, a plastic cover may be added to prevent erosion [7]. As metallic surfaces reflect RF signals, RFID tags will detune near metal resulting in lower read rate. Nagi *et al.* [14] suggests to have as few metallic materials as possible around tags and readers. If this cannot be avoided, metal mount tags with special RF engineering and encapsulation technology may be required [11], which costs up to US\$16.

Combination of Optical and RF Technologies. It is preferred that there is only one ID technology in one system for the ease of operation and management. In the following two situations, we may need to combine optical and RF technologies (i) when it is unaffordable to attach one RFID tag to each item; (ii) when the item-level RFID reading performance declines as it may incur tag reading collision as more tags are being read simultaneously. In the meantime, the possibility of inner tags (there are some obstacles between the tags and the antennas/readers) increases due to packaging limitation. Under the two situations, common practice is that each item is attached with one optical tag and the RFID tag is attached to a certain level of packaging, such as the case, carton, or container. For example, Walmart mandates its suppliers to apply RFID technologies in order to track pallets and cases, and to attach one barcode to each item for identification [15].

ID Coding Level/ID Attaching Level

ID coding level consideration relates to the concept of traceability precision in the supply chain, defined as the smallest unit with a unique ID, which could be item, batch or SKU, and so on. This determines how narrowly one can identify the grouping of material, components or other information associated with products, and logistics [16]. ID attaching level consideration refers to at which product packaging level the ID tags should be placed. ID attaching level has a tight relationship with product logistical and packaging hierarchy [17], from container, pallet, carton, case down to individual item and subpart. According to the traceability standard of GS1 (the leading organization dedicated to the design and implementation of global standards and solutions), each traceable unit should carry a unique RFID. The specific standards for different levels of coding and attaching is specified in Fig. 2 [18].

Lower ID coding (such as item) or attaching level (such as subpart) usually suggests that more detailed information can be recorded, but at the same time it incurs more cost. The basic rule for proper levels is that ID or attaching is implemented at the highest level that is sufficient to achieve the required benefit. For example, the extraordinary financial consequences of the recall crises of Mattel in 2007 are partly due to the improper ID coding level. All the products in the same SKU share the same ID code; therefore, all the products have to be removed from the supply chain as the qualified and defective products cannot be differentiated although only a few batches of toy are defective [19]. According to this fact, on the one hand, if every item has a unique ID code, Mattel may have a chance to largely

Table 2. Performance Comparison of RFID and Barcode

	RFID	Barcode
Line of sight	Not required	Required
Read range	< 100 m	< several feet
Read rate	Multiple (> 100)	One at a time
Read/write capability	Read/write	Read only
Durability	High	Low
Cost	Up to several dollars	Up to several cents

	Precision of the identification

	Level in the logistical hierarchy			

Figure 2. GS1 unique ID standards [18].

reduce excess recalls. On the other hand, item-level ID coding does not help much in this case as most of the contamination occurs in batches, and leads to additional cost, which is difficult to be justified as the toys are up to several dollars per unit. Therefore, in this case, batch-level ID coding is the proper course of action.

Moreover, products with higher value or risk sensitivity should have lower ID coding and attaching levels [9]. This consideration is supported by current industry practice. TAGSYS, the global leader in item-level RFID infrastructure, offers solutions that focus on pharmaceuticals, fashion apparel, quality watches, jewelry, especially in the luxury market, as the item-level investments can only be afforded by those high-end products [20].

DESIGN CONSIDERATIONS FOR READER INFRASTRUCTURE

We highlight three considerations in this section to help select the right readers in order to capture information for a specific application in a cost effective way.

Regional Operating Frequency Allocation

UHF RFID tags and readers have different operating frequencies allocated by different regions, that is, US 902–928 MHz, Europe 866–869 MHz, and Japan 952–954 MHz. Therefore, for global applications, tag design for wide frequency range is crucial and usually the RF engineering has to compromise the tag performance to achieve this [11]. At the same time, multi-frequency readers should be considered for compatibility. Since being unaware of this issue could be extremely expensive for global business, various organizations for standardization and solution providers have been putting efforts to install awareness to practitioners. For example, in February 2009, GSI Hong Kong held “EPC/RFID Technology Live Test in Global Logistics” to enhance users’ understanding of the technical know-how and distribute the implementation experience of the pioneers in the international logistics business [21].

Simple versus Smart

The Intermec report [22] notes that when the RFID application requires capability of local intelligence and peripheral device control, based on the data collected from the tag,

smart readers are the clear choice. When the tag placement, volume, and speed is unpredictable, readers combined with multiple antennas and data filter algorithms could help to increase read rate and real-time local decisions.

If the primary function is to collect and transfer tag data to the backend IT system for further management, simple readers are more cost effective, especially when (i) a local IT system is already available, (ii) the orientation and location of tags are fixed, and (iii) the tag traffic is not busy that not so many tags being read at the same time.

Reader Networking

Existing RFID readers, especially for passive tags, suffer from the performance limitation in the sense of short read range, high power consumption as well as slow and unreliable read rate. For passive RFID applications, if the requirements for the read volume, range, speed, and rate are relatively high, it is important to equip readers with capability to communicate with other readers via concentrators or middleware [11]. This reader network as well as the associated MAC and system level protocol and algorithm designs could help to increase the overall read performance. At the same time, it could help to reduce the total reader amount compared with applying isolated single readers for achieving the same read performance, thereby presenting an opportunity to reduce the overall system costs.

DESIGN CONSIDERATIONS FOR IT SYSTEM

In this section, we focus on information collection, distribution and standardization by considering business characteristics in order to facilitate data retrieving and sharing.

Information Content

It is not true that gathering more information is always satisfactory. Redundant information can sidetrack the decision makers and bring complexity in operation and management. Moreover, excess information consumes more memory and cost. On the
